Two particular advantages of the  $\text{gma}$  system over the bidentate ligands in 1-3 are that the zinc and cadmium complexes, if monomeric, are constrained to have a more or less planar structure similar to that which  $\text{Ni}(\text{gma})$  (diamagnetic) surely possesses, and that they are reducible to monoanions.<sup>40</sup>  $\text{Zn}(\text{gma})^-$  and  $\text{Cd}(\text{gma})^-$  can only be reasonably formulated to contain  $\text{Zn}(\text{II})$  and  $\text{Cd}(\text{II})$  with closed-shell  $d^{10}$  configurations and a coordinated radical-anion ligand and, therefore, should be useful for establishing criteria of metal orbital involvement in the odd-electron wave functions of  $[\text{M}-\text{N}_2\text{S}_2]$  complexes. The  $g$  tensors of  $\text{Zn}(\text{gma})^-$  and  $\text{Cd}(\text{gma})^-$  are isotropic in glasses to the limit of resolution and have values extremely close to that of a free spin.

**(4)  $\text{M}(\text{dtbh})^{0,-1}$  Complexes.** Sodium amalgam reduction of  $\text{Zn}(\text{dtbh})$  and  $\text{Cd}(\text{dtbh})$  affords the monoanions whose  $g$  values are virtually identical with those of the corresponding  $\text{gma}$  species. Values very near the free-electron value are found and no anisotropy is measurable in glasses of 2-methyltetrahydrofuran.  $\text{Ni}(\text{dtbh})^-$  prepared by chemical or electrochemical reduction exhibits isotropic  $g$  values just under the free-electron value and a barely noticeable anisotropy in 2-methyltetrahydrofuran glass which was, however, not sufficiently well resolved to measure. It is apparent that the degree of metal orbital involvement in  $\text{Ni}(\text{dtbh})^-$  is scarcely detectable by epr measurements and is only slightly greater than that of  $\text{Zn}(\text{dtbh})^-$  and  $\text{Cd}(\text{dtbh})^-$ , which is not detectable.  $\text{Cu}(\text{dtbh})^0$  solutions in 2-methyltetrahydrofuran and  $\text{DMF}-\text{CHCl}_3$  give at room temperature a spectrum characteristic of planar  $\text{Cu}(\text{II})$  complexes.<sup>41</sup> Hyperfine splittings due to  $^{63,65}\text{Cu}$  and  $^{14}\text{N}$  are clearly resolved. The spectrum in frozen glasses ( $\sim 85^\circ$ ) is complex and has not been fully interpreted as yet.

**(5)  $\text{M}(\text{dbh})^{0,-1}$  Complexes.** Generation of  $\text{Ni}(\text{dbh})^-$  was accomplished by chemical or electrochemical reduction of the neutral complex. The epr properties of this anion are nearly identical with those of  $\text{Ni}(\text{dtbh})^-$ , viz., an isotropic  $g$  value very near the free-electron value and a barely observable anisotropy in 2-methyltetrahydrofuran glass which is too small to measure. The epr spectrum of  $\text{Cu}(\text{dbh})^-$  is entirely usual for a  $\text{Cu}(\text{II})$  complex with an  $\text{O}_2\text{N}_2$  coordination sphere.<sup>42</sup>

(40) The only zinc complexes of the type  $[\text{Zn}-\text{S}_2\text{S}_2]^+$  which have been reported are  $\text{Zn}(\text{tdt})_2^{+1}$  and  $\text{Zn}(\text{mnt})_2^{+1}$ .<sup>43</sup> No analogous cadmium complexes are known nor are any  $[\text{M}-\text{N}_2\text{S}_2]^+$  species of either metal. Unlike other  $\text{M}(\text{mnt})_2^{+1}$  complexes,  $\text{Zn}(\text{mnt})_2^{+1}$  is very probably tetrahedral,<sup>44</sup> and in acetonitrile or dichloromethane it does not undergo a discrete one-electron oxidation.

2. Akasaka, *J. Chem. Phys.*, 45, 90 (1966), and references

therein. An exception to this statement is found with the radical obtained on bombardment of a single crystal of L-cysteine hydrochloride,  $g_x = g_y = 1.99$ ,  $g_z = 2.29$ : K. Akasaka, *ibid.*, 43, 1182 (1966). The large value of  $g_z$  is attributed to a near-degeneracy of the  $3p_z$  sulfur orbitals, one of which is occupied by the odd electron. A similar situation should not be present in the complexes under consideration.

5. The symmetry of the ground states ( $^1A_g$ ,  $^3B_g$ ,  $^3B_g$ ) concerning our previous analysis does in principle require a threefold symmetry of the  $g$  tensor.<sup>11</sup> Our designation of the  $^3B_g$  ground state probable for these  $[\text{Ni}-\text{N}_2\text{S}_2]^+$  complexes is based only upon isotropies of their  $g$  tensors, which are about the same as those of  $[\text{Ni}-\text{S}_2\text{S}_2]^+$  species.

**Criteria of Metal-Orbital Involvement.** We take as models for the paramagnetic dtbh and gma complexes in which there will be minimal metal orbital involvement in the odd-electron wave functions the monoanions of zinc and cadmium. In the neutral complexes both the ligand and metal have closed-shell configurations. The odd electron added in the first reduction step is then described by what must be an essentially ligand-based MO (*vide infra*). The *g* tensors anticipated approach those of an aromatic free radical. The extent to which sulfur atoms will increase the *g* value above the free-electron value by spin-orbit coupling is difficult to predict. On the basis of available results this effect is slight in aromatic radicals.<sup>44</sup> Accordingly, it is proposed that gma and dtbh complexes having coordinated radical-anion ligands should manifest the following *g*-tensor properties characteristic of aromatic radicals:<sup>48</sup> (i) isotropic values less than  $\sim 2.01$ , and (ii) slight or unresolvable anisotropy. As pointed out elsewhere,<sup>18</sup> when comparing complexes of the same metal with different ligands, it is especially desirable to have measurement of the anisotropic dipole-dipole contribution to the electron-nucleus hyperfine tensor in addition to the principal components of the *g* tensor. However, such information is available only for Ni(mnt)<sub>2</sub><sup>-</sup> so conclusions about metal-orbital involvement can be drawn only from properties of the *g* tensors.

Using these criteria the paramagnetic complexes considered in this work are assigned the ground-state descriptions as shown in Table IV. The classification of Ni(gma)<sup>-</sup> is perhaps least satisfactory. Compared to the [Ni-S<sub>4</sub>]<sup>-</sup> and the [Ni-N<sub>4</sub>]<sup>-</sup> species, this complex has the least metal admixture in the odd-electron orbital, as judged from the smaller *g* anisotropy, such that this orbital is mostly, *but not completely*, ligand-based.

The most striking correlation which is apparent in the classification of the [Ni-S<sub>2</sub>N<sub>2</sub>]<sup>-</sup> complexes is the effect of bridge conjugation on the description of the ground state. This effect is well illustrated by the comparison of Ni(H<sub>2</sub>gma)<sup>-</sup> and Ni(gma)<sup>-</sup>, where the *cis* geometry is maintained. Conjugation of the ligands leads to a striking reduction in the *g* tensor (*cf.* Table III), con-

(44) It is significant to note that  $\langle g \rangle = 2.03$  and  $\Delta g_{\max} = 0.06$  have thus far been observed only in alkylsulfur radicals, where substantial delocalization of the odd spin onto the hydrocarbon portion is unlikely.

sistent with an increase in the ligand character of the half-filled molecular orbital. This correlation has prompted us to deduce from the paramagnetic resonance results a qualitative molecular orbital model for bonding in these complexes.

**Simplified Bonding Model.** *cis*-[M-N<sub>2</sub>S<sub>2</sub>]<sup>+</sup> complexes possess the common chelate ring structure (15) of C<sub>2v</sub> symmetry. The  $\pi$  and  $\sigma$  MO's transform as  $a_1 + b_1$

and  $a_1 + b_1$ , respectively. Symmetries of the metal orbitals are as follows:  $a_1 - d_{z^2}, d_{x^2-y^2}, s, p_x$ ;  $a_2 - d_{yz}$ ;  $b_1 - d_{xy}, p_y$ ;  $b_2 - d_{xz}, p_z$ . Because of the over-all complexity of these systems, we outline what appears to be the simplest possible model. A partial, qualitative MO diagram for [M(dtbbh)]<sup>+</sup>, [M(dtbbh)]<sup>+</sup>, and [M(gma)]<sup>+</sup> complexes is set out in Figure 1a. The orbitals shown are those which presumably will have significant metal character and/or those which will be relevant in ground-state descriptions. The complex metal-ligand orbital mixing allowed by symmetry has been simplified by assuming that, for the purpose of ground-state descriptions, the most important  $\pi$  mixing will involve ligand orbitals which are most nearly non-bonding; these are just those which are the highest filled and lowest vacant orbitals in the dinegative ligand. The energy order, symmetries, and eigenvectors of these orbitals were obtained from a series of Hückel calculations.<sup>46</sup> The results are given in Table V. The coefficients  $c_6$ - $c_{10}$  (not shown) are obtained for the  $a_1$  and  $b_2$  orbitals by multiplying  $c_1$ - $c_5$  by  $-1$  and  $+1$ , respectively. For dtbh, dbh, and gma, the forms of  $\pi^*(a_1)$

(46) To assure the reliability of the energy orders and general forms of the eigenvectors, the ordinary Hückel parameters  $k$  and  $h$  in  $a_i = a + h_i\beta$  and  $b_{ij} = k_{ij}\beta$  were varied over wide ranges in calculations for gma, dtbh, and dbh. Particular attention was given to the sulfur parameters whose suggested values are variant and dependent on the specific system and property under investigation.<sup>47</sup> Representative results were obtained with  $\beta_{CN} = \beta_{NN} = \beta$  and  $\alpha_N = \alpha + 0.5\beta$  for the three ligands. Using these parameters and simultaneously varying  $k_{CS}$  and  $h_S$  over the limits  $0.5 \leq k_{CS} \leq 1.5$  and  $0 \leq h_S \leq 2$ , it is found that for dtbh and gma the energy differences between  $\pi^*(a_2)$  and  $\pi^*(b_2)$ ,  $\pi^*(a_1)$  and the next most stable MO, and  $\pi^*(b_1)$  and the next highest MO are all  $\sim 0.4$ - $0.8\beta$  or more.

		Cd <sup>0</sup>	Cd <sup>-</sup>	Cd <sup>-2</sup>

lata already discussed, it is noted that Ni<sup>0</sup>, Zn<sup>0</sup>, Cd<sup>0</sup> complexes are diamagnetic. No direct evi-e is available relating to the ground states of Cu<sup>+</sup>roup I, Ni<sup>-2</sup> or Cu<sup>-</sup> in group III, and Zn<sup>-2</sup> and in group V. Examining first group II complexes, pr data leave little doubt that the ground states of and Ni<sup>-</sup> are different. Both Cu(dbh) and Cu(i) give characteristic spectra of Cu(II) complexes ig near-axial symmetry. Referring to Figure 1a, complexes are assigned the configuration...-<sub>2</sub>). Ni(dtbh)<sup>-</sup> and Ni(dbh)<sup>-</sup>, on the other hand, ftest spectra not compatible with this configura-

Their csfr formulations are best accommodated erting the order of  $\sigma^*(b_1)$  and  $\pi^*(b_2)$ , leading to onfiguration ...  $\pi^*(b_2)$ . A slight admixture of this MO and/or mixing in other configurations by orbit coupling could account for the just notice-but unresolvable *g*-tensor anisotropy. All MO's

in group I complexes up to and including  $\pi^*(a_2)$  are filled. The configuration of the Ni<sup>0</sup> complexes is presumably ...  $\pi^*(b_2)$ ,  $2\sigma^*(a_1)$ ,  $\pi^*(a_2)$ . The relative order of these orbitals is not known, but the results on group II complexes strongly indicate that they are of lower energy than  $\sigma^*(b_1)$  or  $\pi^*(b_2)$ . In group III the ...  $\sigma^*(b_1)$  configuration for Zn<sup>0</sup> and Cd<sup>0</sup> is assigned. The possibility of triplet ground states, viz.,  $\sigma^*(b_1)$   $\pi^*(b_2)$ , for Cu<sup>-</sup> and Ni<sup>-2</sup> is recognized, but no information is available. The  $\pi^*(b_2)$  configuration is believed to apply to the group IV species. Here metal orbital admixture, as reflected by the epr results, is minimal due to the stability of the effective  $d^{10}$  configuration of the coordinated metal. The  $\pi^*(b_2)$  configuration follows for the species of group V.

Finally, attention is turned to a comparison of Ni(gma)<sup>-</sup> and Ni(H<sub>2</sub>gma)<sup>-</sup>, which have markedly different *g* tensors. For H<sub>2</sub>gma in both the symmetrical (14a, *sym*) and unsymmetrical forms (14b, *unsym*), a series of Hückel calculations similar to those for gma was performed<sup>46</sup> but with  $\beta_{CC} = 0$  and one or both  $\beta_{CN}$  values for the bridge taken as zero. Compared to gma, the absence of a conjugated bridge  $\pi$  system in either structure leads, in any calculation, to a much reduced interaction of the two halves of the ligand system. It is just this effect which is believed to account for the difference in magnetic properties of the two complexes. Because the detailed structure of Ni(H<sub>2</sub>gma)<sup>-</sup> is at present unknown, 14a is selected as the model structure for investigating the effect of bridge hydrogenation on ground-state electronic properties. Use of this structure facilitates a direct comparison with the parent ion, Ni(gma)<sup>-</sup>, for both have idealized C<sub>2v</sub> symmetry. In *sym*-H<sub>2</sub>gma<sup>-2</sup> the ligand orbitals taken to be most important in  $\pi$  mixing with the metal orbitals are  $\pi_L^*(b_2)$  and  $\pi_L^*(a_2)$ , both of which have a Hückel energy of  $0\beta$ .<sup>46</sup> These orbitals have forms similar to 16 and 17 but with no contribution from the bridge carbon atoms (*cf.* Table V). As before,  $\pi_L^*(a_2)$  will mix much more strongly with  $d_{yz}$  than will  $\pi_L^*(b_2)$  with  $d_{xz}$ . A qualitative MO diagram for *sym*-Ni(H<sub>2</sub>gma)<sup>-</sup> showing the orbitals of principal interest is given in Figure 1b.

(48) These are the highest occupied and lowest vacant orbitals in the dinegative ligand. Using the parameters in Table V the next most stable and unstable orbital pairs have energies of 0.5656 $\beta$  and -1.1294 $\beta$ , respectively.

Unlike the case of  $\text{Ni(gma)}^-$ , the differential mixing of  $\pi_L^*(a_2)$  and  $\pi_L^*(b_2)$  with metal orbitals will depend nearly completely on overlap, rather than on a combination of overlap and relative energy factors. This situation will almost certainly lead to the energy order  $\pi^*(a_2) > \pi^*(b_2)$  for  $\text{sym-Ni(H}_2\text{gma)}^-$ , compared to  $\pi^*(b_2) > \pi^*(a_2)$  for  $\text{Ni(gma)}^-$ . Further, the epr results for the former require  $\sigma^*(b_1) > \pi^*(a_2)$  inasmuch as the observed  $g$  tensor does not reveal the near-axial symmetry expected from the  $\sigma^*(b_1)$  configuration. Therefore, the  $\dots \pi^2(b_2)$ ,  $2\sigma^*(a_1)$ ,  $\pi^{*2}(b_2)$ ,  $\pi^{*1}(a_2)$  ground configuration is assigned to  $\text{sym-Ni(H}_2\text{gma)}^-$ , with the order of orbitals more stable than  $\pi^*(a_2)$  unknown. The proposed appreciable admixture of  $d_{yz}$  in this MO results in a situation analogous to the  ${}^2B_{3g}$  states of  $[\text{Ni-S}_4]^-$  and  $[\text{Ni-N}_4]^-$  and to the  ${}^2B_g$  state of  $\text{trans-[Ni-S}_2\text{N}_2]^-$ , and on this basis could account for the observed  $g$ -tensor anisotropy.

### Summary

The principal result of this work is the experimental establishment of  $g$ -tensor properties for coordinated radical anions. For those complexes assigned the csfr formulation, the measured  $g$  tensors suggest the

following order of decreasing metal orbital involvement in the odd-electron wave functions:  $\text{Ni(gma)}^- > \text{Ni(dtbb)}^- \sim \text{Ni(dbh)}^- > \text{Zn(gma)}^- \sim \text{Zn(dtbb)}^- \sim \text{Cd(gma)}^- \sim \text{Cd(dtbb)}^-$ . The persisting problem is the establishment of the quantitative degree of metal orbital involvement in these series of complexes which possess, in the phraseology of Schrauzer and Mayweg,<sup>14</sup> "delocalized ground states." In an experimental epr sense, all that can be presently done is to measure the departure of the  $g$  tensor from its properties in a cation-stabilized free-radical complex toward those expected for a complex in which the electron is essentially metal-localized. At what point the description is changed from ligand free radical to metal-localized radical is currently a subjective matter.<sup>18</sup> As already emphasized, either description is inadequate and neither supplants a complete molecular orbital treatment including configuration interaction and spin-orbit coupling, which produces a ground state demonstrably reconcilable with experiment.

## Theoretical Aspects of the Linear Enthalpy Wavenumber Shift Relation for Hydrogen-Bonded Phenols<sup>1</sup>

Keith F. Purcell and Russell S. Drago

*Contribution from the William Albert Noyes Laboratory, University of Illinois, Urbana, Illinois, and Salem Hall, Wake Forest College, Winston-Salem, North Carolina. Received November 4, 1966*

**Abstract:** The approximation involved in using the observed OH wavenumber shift of phenol upon hydrogen-bond formation as a measure of the magnitude of the interaction has been examined. The equation  $-\Delta H = 0.016\Delta\bar{\nu}_{\text{O-H}} + 0.63$  has been recast in terms of the change in the OH bond energy of phenol on adduct formation,  $\delta E_{\text{OH}}$ , and the energy of formation of the new bond between the donor and the hydrogen  $E_{\text{HB}}$ . The results of molecular orbital calculations (extended Hückel variety) have been analyzed in terms of the bond-energy relationship for the original bond to hydrogen and the hydrogen to base bond. These results provide theoretical justification for the original relationship. Furthermore, this treatment has yielded a parameter which is a quantitative measure of the response of the OH bond of the acid to perturbation by an approaching lone pair of electrons.

In 1962 an enthalpy-OH wavenumber shift ( $\Delta\bar{\nu}_{\text{OH}}$ ) relationship<sup>2</sup> for phenol adducts was presented which involved a wide range of electron-pair donors. The two experimental quantities were related by the equation

$$-\Delta H (\pm 0.5 \text{ kcal mole}^{-1}) = 0.016\Delta\bar{\nu}_{\text{O-H}} + 0.63 \quad (1)$$

The work verified, at least for phenol adducts, the earlier prediction<sup>2</sup> of a linear relationship between the enthalpy of hydrogen-bond formation and OH wavenumber shift. Lippencott and Schroeder<sup>4</sup> several years

ago presented a semiempirical model of the hydrogen bond which also predicted a linear relationship between these two quantities over an enthalpy range of  $-1$  to approximately  $-14 \text{ kcal mole}^{-1}$ . A very slight curvature near the origin was predicted which implied a nonzero intercept on the enthalpy axis upon extrapolation of the linear portion of the curve.

More recently, other workers<sup>5,6</sup> have questioned the validity of this linearity. They have studied weak donor systems which apparently do not obey this relationship. In addition it has been stated<sup>6</sup> that there is no theoretical basis for the existence of such a relationship. This uncertainty has stimulated us to examine the theory of frequency shifts from the point of view

#### Its and Discussion

studying the wavenumber shift-enthalpy relation  
hydrogen-bonding acids, one is faced with the ques-  
of what does the wavenumber shift actually meas-  
nd how is this related to the total enthalpy for the  
ation of a hydrogen bond. It is certainly true  
the change in the force constant of the O-H bond  
henol, for example) is a better measure of the  
ge in the strength of that bond than the wave-  
ner shift because the frequency assigned as the  
"1 stretching vibration" is that determined by at  
a three-body-two-force constant oscillating sys-

One approximation normally made is that kine-  
coupling of the O-H stretching coordinate with  
vibrational coordinates within the acid itself is  
gible or at least invariant under the conditions  
duct formation. Owing to the high energy of the  
stretching vibration and the large mass of the oxy-  
tom, this is a good approximation for C-O, O-H  
ling. Phenol, for example, would be considered  
two-body system with the phenyl ring and the  
n or the oxygen alone acting as a single "atom."  
hydrogen-bonded adduct may then be represented

e B represents the donor atom or molecule and O  
sents the remainder of the acid molecule. A sec-  
approximation that has been made is<sup>8</sup> to ignore  
orce constant of the H...B bond and, hence, to  
the hydrogen-bonded adduct as a diatomic  
mole. This approximation is significantly poorer  
the first because of the small mass of the hydrogen  
but is the one which leads to the use of frequency  
itself as a measure of the change of OH force  
ant or strength of the O-H bond.

McGraw-Hill Book Co., Inc., New York, N. Y., 1955.

Recently, data have become available which allow  
an assessment of this last approximation. Ginn and  
Wood<sup>11</sup> have obtained spectra for carbon tetrachloride  
solutions of phenol containing trimethylamine, tri-  
ethylamine, and pyridine in the region 380-80 cm<sup>-1</sup>.  
They find vibrations in this region which they attribute  
to stretching of the H...B bond: trimethylamine at  
143 cm<sup>-1</sup>, triethylamine at 123 cm<sup>-1</sup>, and pyridine at  
134 cm<sup>-1</sup>.

Using the experimental values of 5.508 sec<sup>-2</sup> for  
 $\lambda_{\text{OH}}$ <sup>2</sup> and 0.012 sec<sup>-2</sup> for  $\lambda_{\text{HB}}$ <sup>11</sup> in the trimethylamine  
adduct and 7.681 sec<sup>-2</sup> for the O-H vibration of the  
phenol monomer,<sup>2</sup> the vibrational secular equations  
were solved for the corresponding force constants.

The solutions to these equations are given in Table  
I. According to these results there is a pronounced  
decrease in the O-H force constant of phenol upon hy-  
drogen-bond formation with trimethylamine.

Table I

	$F_{\text{OH}}$ , mdynes/A	$F_{\text{OH}}^{1/2}$ , mdynes/A <sup>1/2</sup>
$F_{\text{OH}}^a$	7.660	2.76
$F'_{\text{OH}}^b$	5.026	2.24
$F''_{\text{OH}}^c$	5.493	2.34
$F_{\text{HB}}$	0.478	...

<sup>a</sup>  $F_{\text{OH}}$  is the monomer phenol force constant. <sup>b</sup>  $F'_{\text{OH}}$  is the  
"true" adduct phenol force constant. <sup>c</sup>  $F''_{\text{OH}}$  is the adduct phenol  
force constant ignoring the H...B bond.

In comparing  $F'_{\text{OH}}$  and  $F''_{\text{OH}}$  we find that in ignoring  
the H...B force constant a 10% error in  $F_{\text{OH}}$  results  
and that the error in  $F_{\text{OH}}^{1/2}$  is only about 5%. How-  
ever, the difference between these two calculated changes  
in O-H force constant is ~20% (for  $F_{\text{OH}}^{1/2}$  -0.52  
vs. -0.42). The importance of  $F_{\text{OH}}^{1/2}$  will be seen  
shortly. Trimethylamine is one of the strongest bases  
to have been studied with phenol, and this force con-  
stant may be taken as an approximate upper limit for  
H...B bonds in phenol adducts used in the correlation.

It is interesting to compare this value with the N-B  
force constant<sup>12</sup> for (CH<sub>3</sub>)<sub>3</sub>NBH<sub>3</sub> (=2.4 mdynes/A)  
and with the N-H force constant for (CH<sub>3</sub>)<sub>3</sub>NH<sup>+</sup> which  
will be<sup>10</sup> on the order of 5 mdynes/A.

The relationship between the O-H wavenumber shift  
or force constant and enthalpy of adduct formation  
(in a poorly solvating solvent) may now be examined.  
The enthalpy change for the reaction of phenol with a  
Lewis base may be thought of as consisting of two con-  
tributions: the change in the phenol O-H bond energy,  
 $\delta E_{\text{O-H}}$ , and the bond energy of forming the new hydro-  
gen bond to the base,  $E_{\text{HB}}$ .

$$\Delta H = \delta E_{\text{OH}} + E_{\text{HB}} \quad (2)$$

Any nonbonded repulsions which occur between the  
oxygen atom and the base are implicitly absorbed in  
 $E_{\text{HB}}$ . This contribution to  $\Delta H$  will be small but varies  
with the base and is properly considered as one of the  
factors affecting the basicity of a lone-pair donor toward  
a hydrogen-bonding acid. Now a relationship between  
the change in O-H bond energy and the wavenumber  
shift or force constant change is needed as well as a

(12) R. C. Taylor, *Advances in Chemistry Series*, No. 42, American  
Chemical Society, Washington, D. C., 1964, p. 59.

relationship between  $E_{HB}$  and the O-H wavenumber shift. Several authors<sup>13,14</sup> discuss the relationship between  $D_0$ , the bond dissociation energy, and  $\omega_e$  (the harmonic oscillator vibrational energy in  $\text{cm}^{-1}$ ) and  $x_e$  (the anharmonicity constant for that oscillator) for an anharmonic diatomic oscillator

$$D_0 = D_e(1 - 2x_e) = \frac{\omega_e^2}{4\omega_e x_e}(1 - 2x_e)$$

where  $D_e$  equals  $D_0$  plus the zero-point energy. A change in oscillator frequency may then be related to a change in  $D_0$  by

$$\delta D_0 = \frac{\delta \omega_e}{4x_e}(1 - 2x_e)$$

for no change in  $x_e$ .<sup>15</sup> Since  $\omega_a$  (the anharmonic energy in  $\text{cm}^{-1}$ ) is given by

$$\omega_a = \omega_e(1 - 2x_e)$$

$\delta D_0$ , in terms of  $\delta \omega_a$ , is simply

$$\delta D_0 = \frac{\delta \omega_a}{4x_e} \text{ or } \delta E_0 = -\frac{\delta \omega_a}{4x_e} \quad (3)$$

$E_0$  is meant, here, to be the bond energy, and  $\delta \omega_a < 0$  implies that  $\delta E_0 > 0$ . For  $\delta E_0$  in  $\text{kcal mole}^{-1}$ , the above relation is

$$\delta E_0 = -\frac{hcN}{4x_e} \delta \omega_a \quad (4)$$

with Planck's constant in units of  $\text{kcal molecule}^{-1} \text{ sec}$ . Since  $\omega_e$  is given by

$$\omega_e = \frac{1}{2\pi c} \sqrt{\frac{k_e}{\mu}}$$

it follows that  $\delta \omega_a$  and  $\Delta k_e^{1/2}$  are related by

$$\delta \omega_a = \frac{1}{2\pi c} \Delta \sqrt{\frac{k_e}{\mu}} (1 - 2x_e)$$

Rewriting this in terms of an anharmonic force constant,  $k_a$ , one obtains

$$\delta \omega_a = \frac{1}{2\pi c \sqrt{\mu}} \Delta(k_a)^{1/2}$$

The last two equations are identical when  $x_e = 0$ . The relationship for change in  $E_0$  and change in  $k_e^{1/2}$  is given by

$$\delta E_0 = -\frac{hcN}{4x_e} \left( \frac{1 - 2x_e}{2\pi c \sqrt{\mu}} \right) \Delta k_e^{1/2}$$

Some experimental justification for the linear relationship between  $E_0$  and  $\omega_a$  or  $k_a^{1/2}$  for a given bond type has been given by Fox and Martin.<sup>16</sup> Our problem lies in evaluating  $\delta E_0$  for the OH bond in phenol from  $\Delta \nu_{\text{obsd}}$  (the observed wavenumber change) which differs from  $\delta \omega_a$  by virtue of vibrational coupling of the OH and H...B coordinates in the "OH" normal coordinate.

(13) G. Herzberg, "Spectra of Diatomic Molecules," D. Van Nostrand Co., Inc., New York, N. Y., 1950, p 100.

(14) G. W. King, "Spectroscopy and Molecular Structure," Holt, Rinehart and Winston, New York, N. Y., 1964, p 163.

(15) Unfortunately, we are frustrated by both a lack of proper data and a theoretical means to account for variation in  $x_e$  in the adducts.

(16) G. Fox and A. Martin, *Trans. Faraday Soc.*, **36**, 897 (1940); *J. Chem. Soc.*, 884 (1939).

Ideally one would try to observe both  $\nu_{\text{OH}}$  and  $\nu_{\text{H}\cdots\text{B}}$  and carry out a normal coordinate analysis for each adduct as was done for phenol-trimethylamine above. Each analysis would yield  $k_a$  (or  $k_a^{1/2}$ ) and allow the calculation of  $\delta \omega_a$  and  $\delta E_0$  directly for the OH bond. As noted earlier, both vibrational energies are generally not available. Until such data become available one is left to approximate  $\delta \omega_a$  by  $\Delta \nu_{\text{obsd}}$ . The seriousness of the ensuing error is judged by the data in Table I which show that the use of  $\nu_{\text{obsd}}$  for the adduct constitutes a 5% error in approximating  $\omega_a$  in the adduct while the error in using  $\Delta \nu_{\text{obsd}}$  (the change in wavenumber) for  $\delta \omega_a$  underestimates the latter by ca. 20%.

It is interesting to consider at this point the cumulative errors introduced by the Birge-Sponer relationship as applied here (eq 4) and that introduced by setting  $\Delta \nu_{\text{obsd}} = \delta \omega_a$ . The Birge-Sponer method of obtaining  $E_0$  is known<sup>13,14</sup> to overestimate  $E_0$  by ca. 20%. As noted above,  $\Delta \nu_{\text{obsd}}$  is ca. 20% smaller than  $\delta \omega_a$ . The two approximations made here, therefore, will cancel one another to within a few per cent and will, therefore, result in a cumulative error of ca. 5%, say in the value of  $\delta E_{\text{OH}}$  calculated using eq 6 below. The error limits in eq 1 range from ~20% for low  $\Delta H$  to ~5% for the larger  $\Delta H$ . It is therefore seen that this method of obtaining  $\delta E_{\text{OH}}$  from  $\Delta \nu_{\text{obsd}}$  is valid to well within the limits of the original empirical relationship.

It appears that if a more accurate determination of  $\delta \omega_a$  should be made, it must be accompanied by a more accurate relation between  $\delta E_0$  and  $\delta \omega_a$  (that resulting from the Rydberg potential function, for example) if one wishes to maintain an uncertainty of ~5% in the calculated  $\delta E_{\text{OH}}$ .

In order for eq 1 to be theoretically sound there must be a linear relationship between the energy of the base to the hydrogen bond,  $E_{HB}$ , and the destabilization of the O-H bond. From the equations, in which Planck's constant has units of  $\text{kcal sec/molecule}$

$$\Delta H = -\left(\frac{hcN}{4x_e}\right) \delta \omega_{\text{OH}} + E_{HB} \quad (5)$$

and

$$\delta E_{\text{OH}} = -\left(\frac{hcN}{4x_e}\right) \delta \omega_{\text{OH}} \quad (6)$$

one can determine  $E_{HB}$  and  $\delta E_{\text{OH}}$ . This has been done<sup>17</sup> for some literature data<sup>2,5</sup> using  $\Delta \nu_{\text{OH}}$  for  $\delta \omega_{\text{OH}}$ . The results are shown in Figure 1 and Table II. The dotted lines in the figure are the error limits ( $\pm 0.5 \text{ kcal/mole}$ ) reported<sup>2</sup> for the 90% confidence level of the  $\Delta \nu_{\text{OH}}-\Delta H$  relationship. It is seen that  $E_{HB}$  is linearly related to  $\delta E_{\text{OH}}$ , as is required, with a nonzero intercept on the  $E_{HB}$  axis of ~-0.6. It is interesting to note also the reasonable magnitudes of the  $E_{HB}$  for coordinate bonds.

Equation 1 may now be recast as

$$\Delta H = \left(\frac{1}{k'} - \frac{hcN}{4x_e}\right) \Delta \nu_{\text{OH}} + \text{constant}$$

where  $k'$  is the slope of the  $E_{HB}, \Delta \nu_{\text{OH}}$  relationship. In terms of  $\delta E_{\text{OH}}$  ( $\delta E_{\text{OH}} = kE_{HB} + \text{constant}$ ,  $k = (hcN/4x_e)k'$ ) this constant ( $k = -0.682$  for phenol) measures the response of the O-H bond to the effect of an ap-

(17) The anharmonicity constant for *p*-chlorophenol was determined in this laboratory to be 0.0229; the value 0.0227 for phenol was calculated from data in ref 6.

iminary data are available<sup>18</sup> for *p*-chlorophenol low a similar calculation for this acid. The  $\Delta H_{HB}$  plot for this acid has a slope of 0.021, i.e.

$$\Delta H = 0.021 \Delta \nu_{OH}$$

may be interpreted in terms of a larger dipolar con- to the total enthalpy than with phenol ad-

The value of  $k$  for this acid is  $-0.592$  (cf. 2 for phenol), a fact which also indicates that the ond energy change is smaller for this more polar or a given  $E_{HB}$  than in the case of phenol. This

<sup>18</sup> Henneke, private communication.

Figure 2. The overlap populations of the H-F bond and the F-F' "bond" as a function of the overlap population of the H...F' bond: (A) H-F vs. H...F', (B) F-F' vs. H...F'.

may be interpreted in the following ways. (1) The OH bond in *p*-chlorophenol is more resistant to distortion by a lone-pair donor. (2) There is a large contribution to  $E_{HB}$  from dipolar interaction in the case of *p*-chlorophenol. That is, the greater electron-withdrawing property of the *p*-chlorophenyl group results in a higher positive charge on the proton. Both an increased dipolar interaction with electron-pair donors and a less polarizable or less easily perturbed OH bond results. It is interesting to note that this interpretation is very similar to the currently popular "hard and soft" acid concept in that phenol is the softer more distortable acid in the vicinity of the acid site. It is this ability of " $k$ " to reflect the distortability of the electrons in the bond containing the acid atom that makes it such a useful quantity.

While these results are interesting, the question as to why the energy of the hydrogen bond should be linearly related to the change in the energy of the O-H bond still remains. It was decided to attempt an extended Hückel calculation on the hydrogen-bond system (FHF)<sup>-</sup> and to examine the effect on the two fluorine to hydrogen bonds of gradually removing one of the fluorines from the other atom.<sup>5</sup> The use of F<sup>-</sup> was felt to be more realistic and representative of actual hydrogen-bonding situations involving alcohols than the use of O<sup>2-</sup> since the oxygen atoms in alcohols most certainly do not carry a net charge as large as two. The curve derived by Lippencott and Schroeder for O-H...O systems was used to allow for contraction of the HF bond as the second fluorine was removed. The results of our calculations are given graphically in Figures 2, 3, and 4. In Figure 2 we have plotted the overlap population<sup>19</sup> of the short HF bond ( $\rho_{HF}$ ) against the overlap population of the long HF bond ( $\rho_{HF'}$ ). Also included for comparison is the non-bonded F-F' repulsion ( $\rho_{FF'}$ ) (i.e., the negative FF' overlap population). Over the range of F-F' distances 2.49 to 2.80 Å (a range which covers enthalpies of  $-1$  to  $-14$  kcal/mole on the Lippencott-Schroeder curve), these quantities are linearly related.

According to Mulliken's formulation,<sup>19</sup>  $\rho_{ij}$  is proportional to  $\Omega_{ij}$  ("the overlap energy") and the relation-

(19) R. S. Mulliken, *J. Chem. Phys.*, **23**, 1833, 1841, 2338, 2343 (1955); (b) *ibid.*, **36**, 3428 (1962).

Figure 3. The change in overlap energy of the original hydrogen bond as a function of the overlap energy of the new hydrogen bond.

ship is  $\Omega_{ij} = \rho_{ij}\beta_{ij}/S_{ij}$ , where  $\beta_{ij} = H_{ij} - \frac{1}{2}S_{ij}(H_{ii} + H_{jj})$ . We can determine the nature of the  $\Omega_{HF}$  vs.  $\Omega_{HF'}$  relationship by calculating the  $\beta_{ij}/S_{ij}$  values from the results of our iterative calculations. Here we use the definitions

$$\Omega_{HF} = \sum_k (\sum_i \Omega_{iH})k$$

$$\Omega_{HF'} = \sum_k (\sum_i \Omega_{iH'})k$$

where the summations are over the  $k$ -occupied molecular orbitals and the  $i$  and  $j$  ao's of F and F', respectively. The results of these calculations are presented graphically in Figure 3 as a plot of  $\delta\Omega_{HF}$  ( $=\Omega_{HF} - \Omega_{HF'}^0$ ) vs.  $\Omega_{HF'}$ . The slope is  $-0.94$  and the dotted lines are drawn at *ca.*  $\pm 3\%$  tolerance on  $\delta\Omega_{HF}$ . Another point of consistency relates to the behavior of the curve near the origin. Figure 3 indicates that a nonzero intercept is expected for the linear portion of the curve in agreement with the experimental data and the Lippencott-Schroeder model.

It appears that the experimentally determined linearity between  $\delta E_{OH}$  and  $E_{HB}$  is theoretically sound. The slope calculated for the (FHF)<sup>-</sup> model is in essential agreement with that for phenol when one recalls that this slope is sensitive to the nature of the AH bond in the acid (*vide supra*). These results are extremely encouraging and do suggest that the original relationship (eq 1) is not just a fortuitous situation. The linear frequency shift-enthalpy relation originally proposed by Badger and Bauer appears to be valid for phenol when sufficient care is taken to obtain accurate enthalpy data for the hydrogen-bonding interaction.

In this treatment we have been thus far concerned only with the covalent contribution to the bond energies and have neglected, in an explicit sense, any ionic contributions to these energies. Such contributions are extremely difficult to determine with any accuracy and, moreover, some ionic bond character has been included

Figure 4. The Coulombic energy relationship of the two fluorine "atoms."

through the lcao-mo treatment itself. However, in an attempt to gain a qualitative estimate of the nature of the relation of the electrostatic potential energy of one fluorine relative to the other during the retraction of a fluorine, we have calculated the Coulombic potential energies for each fluorine atom with the other and the hydrogen atom for each step in the retraction process. The atomic charges used in this calculation were the atomic charges found in mo calculations. When plotted one against the other (Figure 4), the potential energies are found to be very closely linearly related, and the slope of this line is  $-0.6$ , to be compared with the others.

A qualitative description of the occupied  $\sigma$  molecular orbitals in terms of ao's is given below.

$\infty$  represents a fluorine 2p orbital and  
 $\bigcirc$  represents an s orbital (2s for F, 1s for H).

The  $\sigma$  mo's are found, on the basis of the eigenvectors<sup>20</sup> (see Table III for the eigenvectors for the case

Table III. Eigenvectors for the Case  $R_{FF'} = 2.49$  Å

	F <sub>s</sub>	F <sub>ps</sub>	H <sub>s</sub>	F' <sub>s</sub>	F' <sub>ps</sub>
$\Psi_2$	0.015	0.587	-0.007	-0.006	0.817
$\Psi_7$	-0.125	0.728	0.250	-0.096	-0.511

$\Psi_9$	0.811	-0.007	0.083	0.508	0.003

$R_{FF'} = 2.49$  Å), to involve primarily either fluorine 2p or 2s orbitals with little "hybridization" of the two in any one mo. A series of dots between two ao's indi-

(20) Recall that the basis set ao's have charge adjusted orbital exponents.

Table IV. One-Electron Orbital Energies (ev) of  $\text{HF}_2^-$ 

	$R_{\text{FF}'} = 2.49 \text{ \AA}$	$R_{\text{FF}'} = 2.79 \text{ \AA}$	$\Delta E$
$E(2)$	-18.97	-18.93	-0.04
$E(7)$	-20.24	-20.26	0.02
$E(8)$	-36.37	-36.31	-0.06
$E(9)$	-36.92	-36.98	0.06
$E_{\text{F}}$	-19.28	-19.43	0.15
$E_{\text{F}'}$	-19.08	-18.93	-0.15

es an "antibonding" interaction of the orbitals; a straight line connecting two ao's represents a bonding interaction. The mo's labeled  $\psi_7$  and  $\psi_9$  are bonding with respect to both H-F and H...F';  $\psi_2$  and  $\psi_8$  are H...F' bonding and H-F antibonding. The unoccupied fifth mo is not shown. This result is obtained whenever the HF' distance is greater than the HF distance.

It may also be noted (from the magnitudes of the eigenvectors) that  $\psi_2$  and  $\psi_8$  correspond to "nonbonding" orbitals in the sense that there is little hydrogen 1s involvement. This description is misleading, however, since these orbitals contribute significantly to the HF, F' overlap populations and energies.

In Table IV are given the one-electron energies of the mo's for F-F' internuclear distances of 2.49 and 2.79

Å. The effect of shortening the F-F' distance is as follows:  $\psi_2$  is stabilized,  $\psi_7$  is destabilized,  $\psi_8$  is stabilized,  $\psi_9$  is destabilized. The stabilization of the molecule by changes in  $\psi_2$  and  $\psi_8$  is larger than the destabilization of the molecule by  $\psi_7$  and  $\psi_9$ . The change in H-F bond energy must then be less than the change in H...F' bond energy. We note that the formation of the new bond is more important than destabilization of the old bond and this, of course, is the prime reason for stability of the hydrogen-bonded adduct. Note that  $\psi_7$  and  $\psi_9$  include contributions from the new bond as well as the original bond. Contributions from the strength of the new bond in these molecular orbitals are less than the destabilization of the original bond since the net change in energy of both of these molecular orbitals is in a positive direction.

A comment on the nonbonding  $2p_x$ ,  $2p_y$  orbitals can be made. The data in Table IV indicate that these filled nonbonding  $\pi$ -type orbitals on F are destabilized to the same extent that these nonbonding orbitals on F' are stabilized (move to lower energy). The directions of the changes are a consequence of the decreasing negative charge on F' and the increasing negative charge on F as  $R_{\text{FF}'}$  is decreased.

## Contact-Shift Studies and Delocalization Mechanisms of Nickel(II)-Benzylamine Complexes

Ronald J. Fitzgerald<sup>1</sup> and Russell S. Drago

*Contribution from the William Albert Noyes Laboratory, University of Illinois, Urbana, Illinois. Received January 14, 1967*

**Abstract:** The proton nmr contact shifts of  $[\text{Ni}(\text{bz})_6]^{2+}$  (bz = benzylamine,  $\text{C}_6\text{H}_5\text{CH}_2\text{NH}_2$ ) have been investigated to ascertain whether or not unpaired spin can be delocalized in the phenyl  $\pi$  system when the ligand-metal interaction is essentially  $\sigma$ . The amino, methylene, and aromatic protons are assigned in the nmr spectrum of the complex. The contact shifts and electron spin-nuclear spin coupling constants for these protons are reported. Results obtained from the nmr data show that electron spin is delocalized into the  $\pi$  system of the phenyl group of the ligand. Since the bonding to the ligand is  $\sigma$ , this study shows that contrary to several literature reports one may not assume *a priori* that  $\pi$  delocalization in a phenyl ring is evidence for metal-ligand  $\pi$ -type bonding. A delocalization mechanism which accounts for the observed shifts is presented. The complex with the formula  $[\text{Ni}(\text{bz})_6\text{BF}_4](\text{BF}_4)$  was isolated as a solid. Spectral and conductance data are presented to substantiate that  $[\text{Ni}(\text{bz})_6]^{2+}$  is the species present when the previously mentioned complex is dissolved in nitromethane solutions containing an excess of benzylamine.

The general theory and interpretation of nmr contact shifts has been extensively discussed in a previous publication from this laboratory<sup>2</sup> and should be considered along with the references therein for background information. In this paper, we are specifically concerned with using both the signs and magnitudes of the contact shift for the ligand protons to deduce information about the metal-ligand bonding. The unpaired

spin in most complexes is in a molecular orbital which is essentially a metal d orbital. The extent of mixing of the ligand orbitals with this essentially d metal orbital to form a nonbonding or antibonding mo is taken as an indication of the mixing of the d orbitals with the ligand orbitals in forming the bonding molecular orbital. Hence, by looking at the contact shift, one infers information about the bonding.

Happe and Ward<sup>3</sup> have found proton contact shifts indicating a  $\sigma$  mechanism for delocalizing spin onto pyridine. There have been many reports in the literature,

for example, the work of Eaton, *et al.*,<sup>4</sup> on the aminotroponimineates, where unpaired electron density is delocalized into the  $\pi$  orbitals of conjugated ligands. The authors concluded from this study that there was considerable metal-ligand  $\pi$  bonding. Similarly, the magnitude and direction of the phenyl proton shifts were taken to indicate delocalization of spin into the  $\pi$  orbitals of complexed  $(C_6H_5)_3P$  in  $(R_3P)_2MX_2$  complexes.<sup>5,6</sup> Similar shifts are found for  $[Ni(C_6H_5CN)_4]^{2+}$ .<sup>7</sup> These observations were taken as an indication of metal-ligand  $d\pi-d\pi$  bonding in the phosphine complexes and  $\pi$  bonding in the nitrile complexes.

In the above ligands, the unpaired spin in the  $\pi$  orbitals is transmitted from aromatic ring  $\pi$  orbitals to the protons which are orthogonal to these  $\pi$  orbitals by an atomic exchange coupling mechanism.<sup>8</sup> Levy has proposed<sup>9</sup> that when a methylene group is attached to an aromatic ring, a linear combination of the atomic  $1s$  orbitals of the methylene protons form pseudo- $\pi$ -type orbitals and interact directly with the ring carbon  $p_z$  orbitals. Thus spin is placed directly on the methylene protons through a hyperconjugative-type mechanism. By considering the operation of these mechanisms in reverse, one could place unpaired spin in the  $\pi$  system of the ligand, even though the metal-ligand bond is primarily a  $\sigma$  bond.

In the  $(C_6H_5)_3P$  complex, the phenyl  $\pi$  orbitals are not orthogonal to the phosphorus lone pair, and, if spin were placed on phosphorus by a  $\sigma$  interaction with the metal, it could be placed in the  $\pi$  system by a mechanism similar to that discussed for the methylene group above. In the case of the benzonitrile ligand, spin placed on the nitrogen by a  $\sigma$  interaction could enter the  $\pi$  system by an atomic exchange coupling mechanism similar to that discussed above for protons which are orthogonal to aromatic rings. These arguments, in principle, would offer an alternative explanation to the triphenylphosphine and benzonitrile contact shifts in the nickel(II) complexes and would cast doubt upon the previously cited conclusions regarding  $\pi$ -type metal-ligand bonding. It is difficult to sort out the reported interpretations and the alternatives offered here in the above complexes. In an attempt to ascertain whether or not the alternatives we have offered here are operative, we decided to investigate the contact shifts in  $[Ni(bz)_4]^{2+}$ .

Mixed anion-neutral ligand complexes with benzylamine have been previously reported.<sup>10-12</sup> However, we could find no previous report of the preparation of  $[Ni(bz)_4]^{2+}$  which is described here.

## Experimental Section

**Apparatus.** a. **Nmr Spectra.** The nmr spectra were obtained with Varian Models A-60A, A-56-60, and DP-60 spectrometers.

All nmr spectra were measured relative to TMS as an internal standard.

b. **Visible and Near-Infrared Spectra.** All near-infrared and visible spectra were determined using a Cary recording spectrophotometer, Model 14.

c. **Conductance Data.** The conductance measurements were made on an Industrial Instruments conductivity bridge, Model RC 16B2.

d. **Magnetic Susceptibility Measurements.** The solution moment was determined by nmr at 28° using a method first reported by Evans.<sup>13</sup> The measured susceptibilities were corrected for diamagnetism by the use of Pascal's constant.<sup>14,15</sup>

**Reagents and Solutions.** Hydrated nickel(II) tetrafluoroborate (Alfa Inorganics), anhydrous reagent grade diethyl ether, and reagent grade methanol were used without further purification.

Matheson benzylamine was distilled from BaO under reduced pressure, a constant-boiling middle fraction being selected for use. Aldrich *p*-methylbenzylamine was purified in a similar manner. The ligands were stored in a desiccator containing  $P_2O_5$ .

Fisher reagent grade nitromethane was dried over Linde 3A Molecular Sieves for at least 24 hr.

All additions of ligand were carried out in a drybox equipped with an automatic continuous air flow drying system. When accurate complex concentrations were necessary the materials were weighed in stoppered volumetric flasks and addition of ligand was accomplished by use of Hamilton microliter syringes.

**Preparation of the Complexes.** a.  $[Ni(bz)_4]BF_4(BF_4)_2$ . Aqueous nickel(II) tetrafluoroborate (7.5 g) was dissolved in 20 ml of methanol and then dehydrated by stirring in 50 ml of 2,2-dimethoxypropane<sup>16</sup> for 2 hr at room temperature. Upon addition of diethyl ether to this solution a green oil was formed, which was then redissolved in a minimal amount of nitromethane and allowed to stir again. Upon further addition of diethyl ether to the solution, a light green complex,  $[Ni(MeOH)_4](BF_4)_2$ , was precipitated. This compound was filtered in a drybox and dissolved in 30 ml of benzylamine and allowed to stir for 2 hr. Upon addition of diethyl ether to this solution a blue complex was precipitated. This solution was filtered in the drybox and the complex analyzed. *Anal.* Calcd for  $[Ni(bz)_4]BF_4(BF_4)_2$ : C, 54.4; H, 5.87; Ni, 7.60. Found: C, 54.2; H, 5.80; Ni, 7.80. Infrared analysis detected no water.

b.  $[Ni(p-CH_3bz)_4]BF_4(BF_4)_2$  (*p*-CH<sub>3</sub>bz = *p*-Methylbenzylamine). This compound was prepared by a method analogous to the preceding preparation, retaining the appropriate mole ratios, but substituting *p*-methylbenzylamine in the final step. Here a light blue complex was precipitated. *Anal.* Calcd for  $[Ni(p-CH_3bz)_4]BF_4(BF_4)_2$ : C, 57.3; H, 6.61; Ni, 7.00. Found: C, 57.2; H, 6.67; Ni, 6.68. Infrared analysis detected no water.

c.  $[Zn(bz)_4](BF_4)_2$ . This compound is also prepared in a manner analogous to the nickel(II)-benzylamine complex. A white solid is precipitated here. *Anal.* Calcd for  $[Zn(bz)_4](BF_4)_2$ : C, 50.4; H, 5.44. Found: C, 49.8; H, 5.43.

**Treatment of the Nmr Data.** The complexes studied in this work exchange rapidly with excess ligand. In solutions containing excess ligand a single averaged line position for each proton is observed (*i.e.*, separate complexed and free ligand resonances are not detected).

Although we cooled the solution to its freezing point, -47.8°, we were unsuccessful in our attempt to stop exchange and did not see exchange broadening at this temperature. Thus one may conclude that the fast exchange condition,  $1/T_e \gg \Delta\nu$ , where  $1/T_e$  is the rate of chemical exchange and  $\Delta\nu$  is the shift relative to the diamagnetic complex, is fulfilled at room temperature. The chemical shift of the complex can then be calculated from a knowledge of the stoichiometry of the complex and the chemical shift of the free ligand according<sup>17</sup> to

$$\nu_{\text{obsd}} = \nu_{\text{complexed}}N_{\text{complexed}} + \nu_{\text{free}}N_{\text{free}} \quad (1)$$

where  $\nu$  and  $N$  represent the resonance frequency and mole fraction, respectively.

perature dependence of the contact shift is then given by the Bergh equation<sup>18</sup> (eq 2, modified for the case of protons),

$$\frac{\Delta\nu}{\nu} = -A_n \frac{\gamma_e g \beta S(S+1)}{\gamma_H 3kT} \quad (2)$$

$\gamma_H = 6.58 \times 10^3$ ,  $g = \mu_{eff}/\sqrt{S(S+1)}$ ,  $\beta = 9.27 \times 10^{-21}$ .  $S$  is the sum of the electron spins,  $A_n$  the nuclear spin-spin coupling constant,  $\Delta\nu$  the shift relative to the diamagnetic complex, and  $\nu$  the probe frequency (both in cps), the other having their usual significance.

**Nmr Data.** The proton spectrum of free benzylamine in nitromethane is found to consist of three

Our values for the chemical shift are consistent with those reported by earlier workers<sup>19</sup> for benzylamine in cyclohexane. The results of the nmr studies are listed in Table I.

#### Nmr Spectra in CH<sub>3</sub>NO<sub>2</sub><sup>a</sup>

<i>para</i>	+93	-6.74

relative to the diamagnetic Zn(II) complex at 33°. <sup>b</sup> Calculated  $\Delta\nu$  at 33° using eq 2 and  $g = 2.39$ .

Assignment of these peaks is treated in the Discussion. In addition to the benzylamine complex, the nmr spectrum of [Ni(*p*-CH<sub>3</sub>bz)<sub>2</sub>]<sup>2+</sup> was studied. Peaks assigned to *ortho* and *meta* protons shifted in the same direction relative to free ligand in this complex as those in the benzylamine complex. However, the methyl peaks were shifted downfield in this complex (relative to the free ligand) while the *p*-hydrogen showed an upfield shift in the benzylamine complex. Because of the lower solubility of the *p*-methylbenzylamine complex, we preclude reporting of accurate contact shifts for this complex but approximate values of  $\Delta\nu = +53$ ,  $-77$  cps were obtained for the *ortho* and *meta* protons and *p*-methyl protons, respectively.

## Discussion

**Nature of the Species in Solution.** It is essential for our study to demonstrate that the species in solution is the octahedral complex, and further that there is no equilibrium in solution involving appreciable concentrations of other species.

The [Ni(bz)<sub>2</sub>](BF<sub>4</sub>)<sub>2</sub> compound is light blue. When this compound is dissolved in CH<sub>3</sub>NO<sub>2</sub>, the solution is green, but when excess benzylamine is added the solution turns a darker blue. On the basis of our conductance studies, both the green and blue solutions are clearly 2:1 electrolytes. An analogous process

Figure 1. Nmr spectrum of  $[\text{Ni}(\text{p-CH}_3\text{bz})_4]^{2+}$  plus excess  $\text{p-CH}_3\text{bz}$ .

occurs when DMA is the solvent. We propose that two different species are formed in solution according to eq 3, and that the second reaction is essentially complete for a 1:1 mole ratio of complex and excess benzylamine.

Evidence for the octahedral species is provided by the spectral data. Spectra in both  $\text{CH}_3\text{NO}_2$  and DMA solutions containing excess benzylamine indicate that the same species is present in both solvents. Our conductance data show that  $\text{BF}_4^-$  cannot be coordinated, and therefore the only species common to both solvents must be  $[\text{Ni}(\text{bz})_6]^{2+}$ . Furthermore, addition of excess ligand to a solution of  $[\text{Ni}(\text{bz})_2\text{BF}_4(\text{BF}_4)]$  in a ratio greater than 3:1 does not alter the band positions. The fit of the middle band is somewhat poorer than one might expect for an octahedral complex. However, there is a charge-transfer band on the high-energy side of the  ${}^3\text{A}_{2g} \rightarrow {}^3\text{T}_{1g}(\text{P})$  transition, thus biasing the data in a manner consistent with the error.

Finally plots of  $\nu_{\text{obsd}}$  vs.  $N_{\text{comp}}$ , where  $\nu_{\text{obsd}}$  is the observed nmr frequency in cps and  $N_{\text{comp}}$  is the mole fraction of ligand complexed, give straight-line plots for all the protons of benzylamine indicating that only one species is present in solution, in addition to excess ligand.

These observations lead us to conclude that in solutions of the complex with excess benzylamine the complexed species is indeed  $[\text{Ni}(\text{bz})_6]^{2+}$ .

**Interpretation of the Contact Shifts.** The contact shifts,  $\Delta\nu$  (cps), for all the protons of  $[\text{Ni}(\text{bz})_6]^{2+}$  are reported in Table II. The contact shifts are reported relative to the diamagnetic  $\text{Zn}(\text{II})$  complex. The electron spin-nuclear spin coupling constants,  $A$ , were calculated according to eq 2 and are also listed in Table II. The assignments of the amino and methylene protons in the complex were made by adding excess ligand to the solution of the complex and tracing back to the free ligand value. Because of the line width of the complexed N-H peak, the amino peak can only be detected in solutions containing a large excess of ligand.

Integration of the aromatic proton resonances in the benzylamine complex gave an approximate 3:2 ratio of upfield to downfield peaks. Upon substituting a  $\text{p-CH}_3$  for  $\text{p-H}$ , the  $\text{p-CH}_3$  is shifted downfield, i.e.,

Figure 2. Spin densities on benzylamine protons.

the opposite direction of the  $\text{p-H}$ . This is an indication of a  $\pi$ -delocalization mechanism<sup>20</sup> in the phenyl group and suggests that the upfield peaks be assigned to  $o$ - and  $p$ -H and the downfield peak to  $m$ -H. This assignment is further substantiated by the fact that the peak we have assigned to the *ortho* proton in the  $p$ -methylbenzylamine complex (the upfield peak) is the broadest C-H in the spectrum, as can be seen in Figure 1. It is not possible to assign unambiguously the two upfield peaks in the benzylamine complex to the *ortho* and *para* positions because of their substantial overlap. A tentative assignment is presented, and, as will be seen, this assignment does not alter the conclusions to be drawn. Since octahedral nickel(II) complexes are of cubic symmetry and possess a  ${}^3\text{A}_{2g}$  ground state, the  $g$  tensor should be isotropic and there should be no pseudo-contact interaction.<sup>21</sup> Even though the "true" point group of these complexes is not  $\text{O}_h$ , we may assume any pseudo-contact shifts to be extremely small and neglect them. We can then consider the observed contact shifts to be isotropic shifts and interpret them in terms of spin delocalization mechanisms.

Since there are two unpaired electrons in the metal  $e_g$  orbitals, which are aligned with the magnetic field, a  $\sigma$ -type metal-ligand bond with the amine would place the unpaired spin in the  $\sigma^*$  antibonding orbital. Thus, positive spin density (spin aligned with the field) is also placed on the nitrogen and on all other ligand atoms making a substantial contribution to the  $\sigma^*$  antibonding orbital. This gives rise to a downfield shift at these atoms. The spin densities on the protons, as indicated by the nmr data, are shown in Figure 2. We have the very interesting result that, in a system where the metal-ligand interaction is essentially  $\sigma$ , the distribution of spin density at the phenyl protons is that expected for the  $\pi$ -delocalization mechanism (i.e., alternation of the sign of the spin densities). Clearly then, this experiment indicates that one cannot use distribution of unpaired spin in the  $\pi$  system of the ligand as an indication of metal-ligand  $\pi$  bonding as has so often been done.<sup>5-7</sup> Thus, unpaired spin may be delocalized onto the ligand by a  $\sigma$  mechanism and be placed in the  $\pi$  system by various mechanisms, including one that operates in the reverse of that used by Levy<sup>9</sup> and Copla and DeBoer<sup>22</sup> to explain how spin is transmitted from the phenyl ring to methylene or methyl protons.

Having established the hypothesis this experiment was designed to test, an interpretation of the contact shifts remains. As mentioned previously, the  $\sigma$ -bonding interaction of the ligand with nickel places positive spin density in the  $\sigma^*$  antibonding molecular

(20) A. D. McLachlan, *Mol. Phys.*, **1**, 233 (1958).

(21) H. M. McConnell and R. E. Robertson, *J. Chem. Phys.*, **29**, 1361 (1958).

(22) J. P. Copla and E. DeBoer, *Mol. Phys.*, **7**, 333 (1963-1964).

ls that are formed. Thus a positive spin density is placed on the nitrogen.

Since the methylene protons are not orthogonal to the nitrogen orbitals, spin density can be placed on these protons (*i.e.*, the methylene protons contribute directly to the  $\sigma^*$  molecular orbital). This accounts for the observed positive coupling constant. The methylene group in benzylamine must bear some relationship to the phenyl  $\pi$  system as the methylene groups in pyracene ions.<sup>22</sup> As discussed by a linear combination of methylene protons  $\rho_H = N[\phi_{1s}^A - \phi_{1s}^B]$ , where  $\rho_H$  is the pseudo- $\pi$  orbital,  $N$  is a normalization constant, and  $\phi_{1s}^A$  and  $\phi_{1s}^B$  are the normalized  $1s$  atomic orbitals on the methylene protons) has the correct symmetry to interact directly with the  $\pi$  system of the phenyl ring. Spin in the  $\pi$  system is transmitted directly to the methylene protons through a hyperconjugative-type mechanism. The hyperfine coupling of methylene and methyl protons in many aromatic radicals can be explained on this basis. In benzylamine the methylene protons are part of both the  $\sigma^*$  mo and this extended  $\pi$  system. Consequently, placing a net positive spin density on the methylene protons as described above also places spin density in the phenyl  $\pi$  system. This  $\pi$  delocalization gives rise to positive spin densities at the *o*- and *p*-positions and negative spin density at the *m*-carbon.<sup>23</sup> Spin density may then be transmitted to the aromatic protons by the well-known  $\sigma$ - $\pi$ , C-H spin polarization effect.<sup>8</sup> Thus, we expect negative spin density at the *o*- and *p*-hydrogens and positive spin density at the *m*-hydrogen. The lack of attenuation, the alterations of the coupling constants for the aromatic protons, and the opposite signs of the *p*-hydrogen and *m*-hydrogen shifts indicate that the electron spin is placed in the  $\pi$  system of the phenyl ring.<sup>24</sup> It should be mentioned that a mechanism which involves overlap of the amino and methylene protons and the phenyl  $\pi$  system with the  $t_{2g}$  set of nickel orbitals would result in an opposite sign from that observed for the phenyl and methylene protons. Exchange interactions on nickel would place spin down on the

ligand. Also, a direct overlap of  $t_{2g}$  nickel orbitals with the ring  $\pi$  orbitals would give rise to signs opposite to those observed for the ring protons because of exchange effects on nickel.

The large upfield shift of the amino protons is surprising when compared to the water<sup>25</sup> and methanol<sup>26</sup> contact shifts. One might expect that the amino protons would contribute directly to the  $\sigma^*$  mo in the complex and be deshielded by having spin placed directly on them. Instead they are observed to be shielded. The hydroxy protons in  $[\text{Ni}(\text{H}_2\text{O})_6]^{2+}$  and  $[\text{Ni}(\text{CH}_3\text{OH})_6]^{2+}$  are both deshielded<sup>25,26</sup> by this direct mechanism. The direction of the shift for the amino protons is similar to that reported by Wayland and Rice<sup>27</sup> for hexaamminenickel(II) complexes. These authors conclude that negative spin density reaches the protons by a spin polarization effect. O'Reilly,<sup>28</sup> in discussing spin densities in alkali metal-ammonia solutions, has proposed that the observed negative spin density on the hydrogen results from a node in the wave function of the unpaired electron near hydrogen. Consequently N-H  $\sigma$ - $\pi$  spin polarization effects, formally analogous to the more familiar C-H spin polarization effects, are reported to dominate these proton shifts. Our results are consistent with those reported by these authors.

These conclusions should not be construed to mean that we believe that metal-ligand "back-bonding" does not exist. In general, several lines of experimental evidence are required to substantiate its existence. For example, we have recently<sup>29</sup> reported the existence of back-bonding in some substituted pyridine N-oxide complexes of nickel(II). To draw these conclusions, it was necessary to study the infrared, electronic, and nmr spectra of the nickel complexes and the infrared spectra of some phenol adducts of the ligands.

# The Preparation and Properties of Tetra-, Penta-, Hexa-, Hepta-, and Octaphosphates

E. J. Griffith and R. L. Buxton

Contribution from the Inorganic Chemicals Division, Monsanto Company, St. Louis, Missouri. Received October 21, 1966

**Abstract:** Gram quantities of pure polyphosphates containing from four to eight phosphorus atoms per molecule were prepared. The phosphates were hydrolyzed at pH values of 4, 7, and 11 at 30 and 60°. First-order specific rate constants were determined for the over-all degradation of each compound. The rate constants for the end-group clipping to the next lower phosphate and an orthophosphate and the rate constants for the split-out of trimetaphosphate from the chain phosphates were also determined.

The chemistry of pyro-, tri-, trimeta-, and tetrametaphosphate has been the subject of hundreds of scientific articles during the past 100 years. The chemistry of the complex and complicated mixtures of poly- and metaphosphates contained in amorphous phosphate glasses and crystalline very long chain polymers has also been studied extensively. Despite the large volume of information gathered on the systems which have been studied, very little is known of the specific properties of the condensed phosphates containing more than four phosphorus atoms per molecule.<sup>1-4</sup> The knowledge of the properties of tetraphosphate is not extensive when compared with pyro- and triphosphates, but much valuable information has been gained on this anion during the past 20 years.<sup>5-13</sup>

Phosphates containing more than four phosphorus atoms and less than ca. 500 phosphorus atoms are not phase-diagram entities, and no simple method has been devised to prepare even gram quantities of the pure phosphates. The one exception is calcium hexaphosphate which can be prepared with relative ease.<sup>14,15</sup> The compound is very insoluble and cannot yet be used to obtain useful quantities of soluble hexaphosphate salts, however.

The primary objective of this work is to establish a foundation for the comparison of the hydrolysis of polyphosphates as a function of their molecular size. The work is based on more than 20,000 qualitative and quantitative analyses. It is believed to be as reliable as the state of the science allows today without drastically limiting the number of compounds considered.

## Experimental Section

**Preparation of the Pure Polyphosphates.** Polyphosphoric acid was chosen as a source of polyphosphate anions. The acid was prepared by heating 85% orthophosphoric acid in a gold dish at 400° for 12 hr to yield a polyphosphoric acid with an average chain length near five. The average chain lengths were determined by end-group titrations.<sup>16</sup>

A 200-g sample of the phosphoric acid was dissolved in 2 l. of water, and the phosphate was extracted from the aqueous solution into 3400 ml of a 25% solution of *t*-caprylamine dissolved in xylene. The tertiary amine, Alamine 336S, was obtained from the General Mills Co. The two immiscible solvents were shaken together for 1 hr and then allowed to separate. The aqueous phase was discarded. The desired phosphates were stripped from the amine solution with 500-ml portions of 0.1 *N* aqueous ammonium hydroxide; 10 to 12 fractions removed the desired phosphates. The fractions were analyzed by paper chromatography. At this stage of the extraction each fraction contained three major components. About 50 g of polyphosphoric acid was recovered while 150 g was discarded as ortho- and longer chain phosphates, unwanted for this work.

The solutions of phosphates were stored in a refrigerator at 2° until ready to be reextracted. Before the phosphates could be refractionated, it was necessary to convert the ammonium salts back to the corresponding acids. Samples containing similar quantities of the same phosphates were combined and passed through a cation-exchange column containing 4 lb of Dowex 50W-X4 resin in the hydrogen form. The acidic solutions were then mixed with a fresh batch of 33% amine solution at the ratio of 160 g of amine solution to 500 ml of aqueous phosphate solution. The quantities of course depended on the number of phosphate solutions which were combined. The aqueous phase was again discarded after 1 hr of mixing. The phosphate was stripped from the amine solution with 100-ml portions of 0.1 *N* aqueous NH<sub>3</sub>. In a typical extraction 20 fractions were obtained and the amine was completely stripped of phosphate. At this stage each fraction contained two major constituents. The extraction procedure was repeated with combined fractions containing similar phosphates. The third and usually final fractionation of the phosphate solutions was made in a similar way except the final extraction was made with 0.1 *N* NH<sub>4</sub>NO<sub>3</sub> and the aqueous extract volume was reduced to 10 ml. The fractions contained one major fraction, a smaller quantity of a second phosphate, and traces of longer chain phosphates.

When only two major constituents must be separated, an anion-exchange chromatographic column may be heavily loaded and still give satisfactory separation of the two components. A column 1 cm in diameter with 27-cm bed depth was filled with Dowex 1-X8 resin in the chloride form.<sup>17</sup> The column was treated with 400 ml of 0.30 *N* KCl solution adjusted to pH 5.0 with HCl. Then the column was loaded with 0.5 g of ammonium polyphosphates contained in 50 ml of the solvent extracted from the amine solution. The concentration of the eluting agent used depended upon the phosphates to be separated. If the solution contained tetra- and penta- or penta- and hexaphosphate, the column was eluted with

(16) J. R. Van Wazer, E. J. Griffith, and J. F. McCullough, *Anal. Chem.*, **26**, 1755 (1954).

(17) H. L. Rothbart, H. W. Weymouth, and W. Rieman, *Talanta*, **11**, 33 (1964).

V KCl adjusted to pH 5. If hexa- and heptaphosphates were separated, the concentration of KCl was adjusted to 0.35 *N*;  $\gamma$ - and octaphosphates were to be separated, the KCl concentration was increased to 0.40 *N*. When the longer chain phosphates (hexa-, hepta-, or octa-) were to be separated, the column was treated with 400 ml of 0.3 *N* KCl to remove any shorter chain phosphates, and then the concentration was increased to the separation level.

The flow rate of the column was adjusted to 1 ml/min and 20 ml fractions were collected with an automatic fraction collector. After the first 90 fractions had been collected, the phosphate was separated by spotting a drop of each fraction on a filter paper and developing the filter paper as though it were a paper chromatogram which had not been subjected to solvent separation. After the phosphates were located, the midfractions were chromatographed to ensure the purity of the fractions. Like fractions were then combined, and the water was removed from the solution on a thin-film vacuum evaporator connected to a water aspirator. The flask of the evaporator was maintained at approximately 40°. Evaporation was discontinued when the first crystals of KCl appeared in the flask.

Dialysis was used to separate the KCl from the phosphate solution. The saturated solution of KCl was put into a dialysis membrane, 0.75  $\times$  10 in., and then the membrane was suspended in 4 l. of distilled water. The removal of the KCl was rapid and complete. In 3 hr, with three changes of the outside water, the chloride ion inside the dialysis tube was barely detectable. This method was found to be superior to the various precipitation techniques based on benzidine,<sup>1,2</sup> because the phosphate suffered no detectable degradation in this process and no foreign ions were added to the phosphate solution. Once the phosphates were concentrated and separated from the KCl, they were stored in a refrigerator at 2° until analyzed.

Polymers of polyphosphates can be preserved much easier than they can be as the amorphous solids which form either a sodium or potassium salt is precipitated. In every attempt to separate the sodium or potassium salts reorganized within a few days if the salts were stored as the solids. If the crystalline salts of either the guanidinium or acridinium phosphates were used by the methods Quimby<sup>4</sup> employed to crystallize the tetraphosphate, they were stable if care was taken to make certain that the salts were dry.

**Analysis of the Phosphates.** It has been well established that the polyphosphates do truly exist and can be separated as pure substances by chromatographic techniques.<sup>18</sup> It is not considered necessary to attempt to reestablish this fact. The analytical problems which were confronted were quantitative rather than qualitative.

Qualitative methods<sup>19-22</sup> were needed which were reasonably accurate and at the same time reliable if the large number of analyses were needed in a hydrolysis study were to be handled within a reasonable time limits. After several hundred tests with columns, thin-layer chromatograms, and thin-layer chromatograms, the decision was made to employ ascending paper chromatograms on a 10  $\times$  11.5 in. sheet of Schleicher and Schuell 589 Orange Ribbon paper. The paper has the advantage of being easily referenced and graphic. Paper chromatograms are also graphic, but quantitative analyses of phosphates were more difficult.

For acidic chromatographic solvent 92-D recommended by Griffith<sup>21</sup> was used in this work but it was modified in one respect. Separations were obtained with the longer phosphates if solid ammonium carbonate was substituted for the aqueous ammonia solution suggested. For solvents designed to separate hepta-, octa-

and nonaphosphates, 1.4 g of ammonium carbonate was used per 1 l. of solvent solution, while the solvents used to separate the shorter chain phosphates (tetra-, penta-, and hexa-) required 2.5 g of  $(\text{NH}_4)_2\text{CO}_3$ /l. The basic solvent used in the two-dimensional chromatograms was that recommended by Karl-Kruppa.<sup>20</sup> The chromatographic chambers were standard 6  $\times$  12 in. cylinders and contained 100 ml of solvent. The chromatographic chambers were thermostated at 17° in a modified commercial deep freezer equipped with a forced air fan. The temperature-sensing element in the refrigerator was replaced with a thermistor and an electronic relay to improve the temperature control of the freezer.

The phosphate solution to be tested (10–20  $\mu$ l) was placed 1.25 in. from the bottom of the filter paper as a band 0.75 in. long and 1/8 in. wide. Each chromatogram held four spots or two duplicated samples. Attempts were made to store chromatograms at 2° while awaiting a vacant chromatographic chamber, but this technique caused errors if the chromatograms were stored for more than 24 hr because the phosphates degraded on the paper.

Chromatographic papers were allowed to remain in the chromatographic chamber for about 12 hr or until the solvents reached the top of the chromatograms. The chromatograms were then removed from the chambers, air-dried, and then dried for 5 min at 100° in a forced air oven.

The chromatographic sprays used to develop the chromatograms were those recommended by Hanes and Isherwood.<sup>23</sup> At this point the treatment of the chromatogram depended upon its ultimate use. Parts of the chromatograms were quantitatively analyzed for the per cent of the phosphorus in the phosphate in question compared to the remainder of the phosphate on the chromatograms. These chromatograms were analyzed by the method recommended by Smith,<sup>24,25</sup> using a Spectronic 20 spectrometer manufactured by the Bausch and Lomb Co. The spectrometer was fitted with a digital readout supplied by the same manufacturer.

Other chromatograms were analyzed for the distribution of phosphate species to give a total analysis of the phosphates. These chromatograms were analyzed by the method recommended by Bernhart and Chess,<sup>27</sup> and an Analytrol-RB spectrometer manufactured by the Beckman Instrument Co. was employed to perform the analyses. The latter method of analysis was not as accurate as the extraction technique, but a quantitative analysis was obtained for all species present. Hydrolyzing samples of octaphosphate contain as many as nine species, and the time required to obtain an analysis of each phosphate by the extraction technique was prohibitive. The two methods agreed within about 2% per species analyzed except for an occasional analysis when the errors, which we attributed to the authors, resulted in complete disagreement between the two methods. The data were discarded when the errors greater than about 2% per phase were committed.

**The Rates of Hydrolysis of Polyphosphates.** Nearly 100 papers have been published on the rates of hydrolysis of condensed phosphates yet only three works have been reported for the hydrolysis of individual polyphosphates longer than tetraphosphates.<sup>1,4,6</sup> Even the hydrolysis of tetraphosphate has received but little attention,<sup>3,4,6</sup> while only two works have been published on the hydrolysis of higher ring metaphosphates.<sup>34,35</sup> Pyrophosphate has been studied in great detail.<sup>36-71</sup> The complex glasses, very long chain

In the work presented here the rates of hydrolysis were determined for tetra- through octaphosphates at pH values of 4.0, 7.0, and 11.0 at 30 and 60°. The concentrations of the polyphosphate solutions were adjusted to allow for a convenient analysis by paper chromatography since there was no obvious reason for adjusting the concentrations to any other values. The concentration of phosphate was adjusted as near to 50 µg of phosphorus per 10 µl of solution as was convenient; however, no differences in the data obtained could be attributed to changes in concentration of the phosphate even if the concentration was increased or decreased by as much as 200%.

Before the phosphates were hydrolyzed, they were converted from the potassium salts to either the sodium or tetramethylammonium salts. The conversion to the sodium salt was accomplished by passing the phosphate over a large excess of Dowex 50 resin which was converted to the sodium form with 0.2 N NaOH and then washed with distilled water until the wash water was no longer basic. The column used was simply a 100-ml buret which had been cut to 20 ml and contained 10 ml of dry resin. A similar technique was used for the tetramethylammonium conversion except the phosphate was first converted to the acid form with the cation-exchange resin, and then the phosphate was neutralized with 3% tetramethylammonium hydroxide. This was done to keep the excess tetramethylammonium ion concentration as low as possible.

Samples of 2 ml were found to be convenient for the hydrolysis studies. The samples were adjusted to the required pH with the aid of a Beckman Model G.S., battery-powered, pH meter. The usual precautions were observed and the pH was adjusted to within 0.01 unit of the required value. No sodium ion corrections were applied. After the pH was adjusted to the proper value the sample was transferred to a 2-dram glass vial, which was then placed in a thermostated water bath. The baths were obtained from the E. H. Sargent Co., but the thermoregulator was replaced by a more sensitive unit obtained from the H and B Instrument Co. The baths were capable of maintaining 30.00 ± 0.01 or 60.00 ± 0.01° for as long as 2 years without readjustment. The pH was maintained by periodic adjustments back to the original value when required.

The time the samples were maintained in the baths and the time at which samples were collected was monitored by two master interval timers. At the start of each hydrolysis experiment the local time was recorded, as well as the time on the master timers. The time was recorded to 0.1 hr in all cases except the very fast reactions where the time was measured in minutes.

A zero-time analysis was made on each sample before it was placed in a thermostat. If any trace of a higher polyphosphate than the one under consideration was found in a sample to be hydrolyzed, the sample was repurified. The shorter chain lengths caused no difficulties in the determination of rate constants. The presence of phosphates with chain lengths greater than the phosphate under consideration could not be accepted because there was no simple way to correct the errors caused by their degradation before their rate constants were known. At prechosen intervals, samples were withdrawn from the vials and analyzed. On the average eight data points were collected for each rate constant. Two types of chromatograms were prepared and each chromatogram was duplicated and placed in reserve in case an analytical result was questionable. The reserves were not maintained for more than 24 hr at 2° or they were considered to be useless. One-dimensional chromatograms were used to establish the per cent phosphorus present as the polyphosphate under study vs. the remainder of the phosphate contained in the sample being studied.

The duplicate half of the same chromatogram was analyzed by the Analytrol to give the percentage phosphorus present as the

various degradation products if it was not needed as a duplicate or the single species analysis. A two-dimensional chromatogram was also set up to determine the percentage trimetaphosphate which formed from the longer chain phosphates. The two-dimensional chromatograms were divided into three parts: the phosphate under study, the trimetaphosphate, and the short-chain phosphates which were degradation products. This selection of samples gave an independent check in the values obtained from the one-dimensional chromatograms.

The analyses of samples are so involved and the possible sources of error are so numerous that no attempt will be made to discuss them. The reader is referred to the literature cited from which the analytical techniques were adopted. An estimate of the errors committed in determining the rate constants was made at the 95% confidence limits. These estimates reflect more the precision of the work than its accuracy. Rather than attempt to assign a more or less meaningless estimate of error to each rate constant, it can be safely stated that the error is less than  $\pm 10\%$ . Much more effort was expended by the authors to furnish a self-consistent group of data than to attempt to supply highly reliable data with tools that are inherently difficult to control. For this reason the rate constants developed in this work will be reported to only two significant figures. The reader can gain much greater feeling for the errors in the work by comparing the various plots of the rate constants vs. pH or chain length.

No major difficulties were encountered in the analyses of the sodium polyphosphates but the tetramethylammonium polyphosphates were particularly difficult to analyze when the longer phosphates were chromatographed. The major difficulty arises from the fact that the tetramethylammonium hexa-, hepta-, and octaphosphates streak badly in the chromatographic solvents which separate them within 12 to 16 hr. A second difficulty results from the tetramethylammonium ions which impart a blue color to a chromatogram when developed with the ammonium molybdate reagent used in this work. No method was devised to overcome these two sources of error, and the tetramethylammonium phosphate work was limited. The data obtained with the tetramethylammonium phosphates are reported but the errors are twice as large as those for the sodium polyphosphates.

The need for the tetramethylammonium data vs. sodium ion data has been discussed in a previous work.<sup>10</sup> It will be noted that there are several notable differences in the sodium phosphate data and the tetramethylammonium phosphate data.

Table I contains the first-order specific rate constants, for the overall disappearance of a phosphate species,  $k_t$ ; the first-order rate

constant for the disappearance of a species by the clipping of an orthophosphate from the end of a chain,  $k_e$ ; and the first-order rate constant for the disappearance of a species by the splitting out of a trimetaphosphate from the linear polyphosphates,  $k_m$ . Both  $k_t$  and  $k_m$  were obtained from the analytical data. The end-group clipping rate constants were calculated from

$$k_t = k_e + k_m \quad (1)$$

$$-\frac{dC}{dt} = k_t C = (k_e + k_m)C \quad (2)$$

where  $C$  is the concentration of the species in question. In the calculations used in this work,  $C$  was expressed as the percentage of the phosphorus in the phosphate under consideration with respect to the total phosphorus in the sample solution.

## Discussion of Results

To compare the various phosphates the authors plotted the data on two types of graphs. The first plot was  $\log k$  vs. pH for each phosphate species at each temperature. The second plot was  $\log k$  vs. the number of phosphorus atoms contained in the phosphate at a fixed temperature and pH. The conclusions drawn from these data are based upon these graphs, but unfortunately they are too numerous to reproduce. It is recommended that the reader seriously interested in the results plot the data himself.

The rates of degradation of sodium hexa-, hepta-, and octaphosphates by all routes simultaneously are greater at pH 7 than at pH 4 or 11. It was not unexpected that the over-all degradation at pH 11 was less than it was at pH 7, but it was unexpected that the rate at pH 7 was greater than it was at pH 4 as seen in Figure 1.

In every case tested the degradation of the phosphates followed the first-order rate law with respect to the reacting phosphate. No extensive effort was made to prove that the first-order law was observed, but the

Figure 1. Specific rate constants for sodium polyphosphates as a function of pH at 60°: pyro- and tri- values from ref 59.

data contained no results which caused doubt that the first-order law was obeyed with the longer chain phosphates as it is with the shorter chain phosphates. The rate constants of Table I were derived from straight lines obtained when  $\log C$  was graphed as a function of time. For test cases the straight-line relationship was maintained for three or more half-life periods. All of the rate constants, except the very small constants, are derived from data gathered during at least two half-life periods.

The stabilities of the polyphosphates decrease as the chain lengths increase, but the rate constants seem to be approaching some limiting value as chain length increases. The differences between the rate constants for tri- and tetraphosphates are much larger than the differences between hepta- and octaphosphates under the same experimental conditions as shown in Figure 2.

It is known that a chain phosphate may degrade by any one of at least three routes.<sup>95</sup> One mode of degradation results from the clipping of the end group of the chain to form orthophosphate and a phosphate chain one phosphorus atom shorter. A second mode is the degradation by the breaking of the chain somewhere in the middle of the chain to yield two chains. A third method of degradation results from the splitting out of a trimetaphosphate ring to leave a chain phosphate three phosphorus atoms shorter. Although the first and third methods of degradation were clearly evident, there were no clear indications when the total families were considered that the chain cleaved in the middle.

Rate constants were developed for the loss of the polyphosphates by splitting out trimetaphosphate. As shown in the midcolumns of Table I, the rates of loss of a phosphate by this route can be as great or greater than the loss by the hydrolysis of the ends of the chains.

The shortest chain phosphate which can degrade to trimetaphosphate is tetraphosphate. Only trimeta- and orthophosphate would remain. In the work with

Figure 2. Specific rate constants for the total reaction of sodium polyphosphates as a function of molecular size at pH 4.0 and 60°: pyro- and tri- values from ref 59.

tetraphosphate, there was a small but detectable buildup of trimetaphosphate in the solutions. The concentrations of the trimetaphosphate was too small to yield reliable rate data. When the chain length of the phosphate was five phosphorus atoms or more, the buildup of trimetaphosphate was easily measured and rate constants were developed.

In the past there has been considerable speculation as to the mechanism of the "hydrolysis" of a chain phosphate to trimetaphosphate. It is the contention of the authors that this degradation is not hydrolysis at all but a reorganization of the phosphate as occurs in anhydrous systems when phosphates are heated. It can be seen that water need not be considered as a reactant. For example, the degradation of sodium hexaphosphate to trimetaphosphate and triphosphate may be represented as

and water is neither a reactant nor a product. In fact, a 1:1 mixture of trimetaphosphate and triphosphate is exactly the mixture one would expect from phase-diagram considerations<sup>124</sup> if an anhydrous sodium phosphate with a hexaphosphate composition were heated to speed the approach to equilibrium conditions.

The relationships among the rate constants for the tetramethylammonium phosphates were of a different form when compared to the corresponding sodium systems when a graph of  $\log k_t$  vs. pH was constructed. This led to the conclusion that perhaps trimetaphosphate was not being formed in the tetramethylammonium systems as it was in the sodium systems. Heptaphosphate was converted to the tetramethylammonium salt and degraded at pH 11 and 60°. Small quantities of trimetaphosphate buildup could be

(124) E. P. Partridge, V. Hicks, and G. W. Smith, *J. Am. Chem. Soc.*, **63**, 454 (1941).

ed during the study, but the concentration of triphosphate was never large enough to obtain a tentative analysis of this species. It is doubtful tetramethylammonium trimetaphosphate would even if anhydrous tetramethylammonium heptahate were heated to temperatures just high enough se it to reorganize. It can only be concluded that dium ions in the sodium polyphosphate system buted to the formation of the trimetaphosphate rms as a degradation product of the reaction.

activation energies for the degradation of a polyhate to trimetaphosphate are independent of the length of the phosphates from which the triphosphate forms. Conversely, the activation enare very dependent upon the pH of the solution. ctivation energies increase as the pH of the soluincreases (see Table I).

e the rate constant  $k_t$  (for the total reaction by all ) has been obtained and the rate constant for lit-out of trimetaphosphate,  $k_m$ , is known, the onstant for end-group clipping,  $k_e$ , can be calcu-

The rate constant for end-group clipping,  $k_e$ , difference between the rate constant for all ns,  $k_t$ , and the rate constant  $k_m$ .

rate data for the end-group clipping at pH values id 7 are in accordance with similar data developed r works with pyro-, tri-, and tetraphosphates.<sup>4,59</sup>

4 there are small differences between the values rate constants for the total reactions and the onstants for end-group clippings since the phosdegrades mostly by end-group clipping. Sigtly different data were obtained for the end-clipping at pH 11. At pH 11 the rates of deon by end-group clipping are independent of the length above five phosphorus atoms. The values for hexa-, hepta-, and octaphosphate are all the at pH 11 and 60°. The same is true for penta-, hepta-, and probably octaphosphate at pH 11 °.

activation energies for end-group clipping de-with increasing pH for each phosphate. This or was noted for sodium triphosphate<sup>59</sup> in a pre-report. The activation energies for sodium trihate at pH values of 4, 7, and 10 are 27.6, 28.0, .8 kcal, respectively.

data for the tetramethylammonium phosphate s are not sufficiently complete to draw many ant conclusions. The activation energies for al reaction of pentaphosphate are similar in value sodium system at pH 4 and 7, but the large in-in activation energy at pH 11 was not found in ramethylammonium system. This is attributed : observation that trimetaphosphate split-out ot occur to any appreciable extent in the tetrammonium system. In the sodium system pH increased, the temperature sensitivity of the aphosphate split-out became greater while the ature influence of the end-group clipping del sharply.

nerous studies have shown pyrophosphate is more in aqueous solutions than triphosphate. It has een demonstrated that triphosphate is more than tetraphosphate. The hydrolyses of shorter phosphates are catalyzed by hydrogen ions but hydroxyl ions, but the hydrolysis of the lower

membered ring phosphates, trimeta- and tetrametaphosphate, is catalyzed by both hydrogen and hydroxyl ions. No satisfactory explanations of these facts are known. This has probably resulted from the fact that the longer chain phosphates have been so difficult to prepare that no one has had the opportunity to compare the phosphates as a family at a variety of pH and temperature values.

The electron density about a POP linkage in a phosphate is very dependent upon the degree of polymerization of the phosphate in which it occurs. Kinetically, the most stable chain phosphate in aqueous solutions is pyrophosphate. The POP linkage in pyrophosphate is also the most electron-rich phosphate linkage possible. If one neglects the inner shells and considers the octet about the oxygens only, there are 56 electrons associated with the linkage. On the other hand, the most unstable of all phosphates in aqueous solution is phosphorus pentoxide,  $P_2O_{10}$ . This molecule has the minimum number of electrons per POP linkage it is possible for a phosphate to contain, namely 13.3 per POP linkage, neglecting the inner shells. These facts would surely lead one to believe there is a relationship between the electron density of a POP linkage and its stability in aqueous solutions. Table II shows the average number of electrons per POP linkage for the phosphate family.

**Table II.** The Electron Density of POP Linkages in Condensed Phosphates

Compound	Electrons in valence shells per POP linkage
Pyrophosphate	56
Triphosphate	40
Tetraphosphate	34.7
Pentaphosphate	32
Hexaphosphate	30.4
Heptaphosphate	29.3
Octaphosphate	28.6
Trimeta-, tetrameta-, pentameta-, etc., or long-chain phosphate	24.0
Phosphorus pentoxide	13.3

Data are available for the first time to test the concepts presented above; it is desirable to ask under what conditions the concept should be tested. Reflecting upon the behavior of the longer chain phosphates makes it obvious that only the pH 4 data are of use, because the longer chain phosphates degrade by two routes at pH values of 7 and 11. At pH 4 the predominant reaction is end-group clipping. Figure 3 is a graph of the  $\log k_e$  at pH 4 and 60° vs. the average number of electrons per POP linkage. The values for pyro- and triphosphates were taken from the work of Van Wazer, Griffith, and McCullough.<sup>59</sup> The 30° data treated in the same manner also yield a straight line but of greater slope.

Figure 3. Specific rate constants for end-group clipping of sodium polyphosphates as a function of the average number of electrons per POP linkage: pyro- and tri- values from ref 59.

The number of electrons per POP linkage in a polyphosphate approaches the number of electrons per POP linkage in a ring metaphosphate as a limit, *i.e.*, 24.0 as the chain length of the polyphosphate approaches infinity. It is therefore possible to place an upper limit on the rate of hydrolysis of a long-chain phosphate as the phosphate degrades by end-group clipping in acidic media.

It is not surprising that pyrophosphate is the most stable of all phosphates in basic media. Moreover, since the ring metaphosphates have an intermediate number of electrons per POP linkage, these substances suffer both nucleophilic and electrophilic attacks.

The electron density per POP linkage is not the complete story on phosphate hydrolysis, however. The ring

metaphosphate's POP linkages are all isoelectronic, no matter how large or small the ring may happen to be. As previously shown by the authors,<sup>34</sup> the rate of degradation of a ring phosphate decreases as the size of the ring increases. The true ring hexametaphosphate is the most stable phosphate ever studied near neutral pH values. Unmistakably there are entropy considerations as well as electron-density considerations. The larger rings are resistant to hydrolysis because they are more flexible than the smaller rings and can distribute and dissipate the energy of collision as is evident from the very low activation energies for the hydrolysis of the large-ring phosphates.

Throughout the discussion of this work attention has been focused upon the rate of disappearance of a single species of phosphate without regard to the over-all degradation products. In a following article the phosphates will be treated as a family. Not only will the single species be considered, but also the relative concentration of the various degradation products which occur. Also a method was developed which allows one to predict the concentration of various species as a function of time based upon the simultaneous consideration of the rate constants presented in this work.

The data of this work were not treated as individual protonated species as has been done on several occasions with pyrophosphates.<sup>56,62,125</sup> The treatment of protonated species is more mathematical than experimental and can easily be derived from these rate data and published *pK* values of the condensed phosphates<sup>126</sup> by modern computer techniques.

## Machine Computation of Equilibrium Constants and Plotting of Spectra of Individual Ionic Species in the Pyridoxal-Alanine System<sup>1</sup>

Kozo Nagano<sup>2</sup> and David E. Metzler

*Contribution from the Department of Biochemistry and Biophysics, Iowa State University, Ames, Iowa 50010. Received February 1, 1967*

**Abstract:** A method is described by which a digital computer with an automatic plotter can draw a smooth curve to fit experimental spectral data points at 5-m $\mu$  intervals with supplemental points, where needed, at 2.5-m $\mu$  intervals. Programs have been written that compute, from spectral data at up to 75 wavelengths, as many as three successive dissociation constants for a light-absorbing compound. A least-squares method involving successive approximations is used to obtain the best fit of all pK values to 0.01 unit. The spectra of the individual ionic forms (up to four) are drawn, and the extinction coefficients are also punched out on cards. New data for pyridoxal at 50° are reported. Equilibria involving a second nonlight-absorbing component and reversible formation of a compound or complex are also considered. Methods are provided for finding the formation constant, the successive acid dissociation constants, and the absorption spectra of individual ionic forms for the compound or complex. The graphs of the log of the apparent formation constant *vs.* pH and the pH profiles of the concentrations (or percentages) of individual ionic forms are drawn automatically. An additional program provides for the plotting of experimental spectral data, together with calculated spectra, and the plotting of experimental data and calculated curves of absorbance *vs.* pH at any desired wavelength. Two systems involving formation of Schiff's bases are analyzed in detail.

Measurements of absorption spectra are used frequently to evaluate equilibrium and rate constants in complex chemical and biological systems. The availability of precise recording spectrophotometers makes it feasible to collect data over a broad range of wavelengths, but often, to simplify calculations, data at only one or a few selected wavelengths are employed in the computations.

The use of digital computers for the analysis of chemical equilibria has been developed by de Maine and Swain,<sup>3</sup> Sillén and Ingri,<sup>4</sup> Conrow, *et al.*,<sup>5</sup> Sullivan, *et al.*,<sup>6</sup> and Wiberg.<sup>7</sup> With a modern high-speed computer, it is possible to treat very complex systems in which numerous equilibria of dissociation of protons and formation of complexes are taken into account. It is feasible to use spectral data at many wavelengths in such computations, and to obtain a graphical display of the results with an automatic curve plotter.

This report describes a method by which a digital computer with an automatic plotter fits a smooth curve to experimental points to closely reproduce the complete electronic spectral absorption curve of a substance. This method when used in conjunction with an appropriate computational program permits the evaluation of acid dissociation constants and formation constants for complexes and compounds and the automatic plotting of the spectra of individual ionic species. It also provides a direct comparison between experimentally observed spectra and those predicted from the equilibrium constants and the spectra of the individual ionic species. Dissociation constants and spectra of individual ionic forms have been evaluated for vitamin B<sub>6</sub> aldehyde (pyridoxal) at 50° and for 5-deoxypyridoxal at 25°. The system pyridoxal-alanine at 50° has been studied in detail and formation constants and acid dissociation constants for Schiff bases are presented for this system and for the system 5-deoxypyridoxal-leucine at 25°.

The approach described should be of use in studying many different problems of chemical equilibria. Programs will be made available to persons desiring them.

### Recording and Plotting of Spectral Data

Data are transcribed from the tracings obtained with a standard recording spectrophotometer. If spectra change with time as a result of slow chemical reactions (e.g., between pyridoxal and alanine) it is necessary to extrapolate the spectra to zero time to analyze the initial equilibria. This is accomplished by measuring the spectra repeatedly at intervals of 10, 30, 60, 90, 120, and 180 min after mixing. The computer makes a linear extrapolation, taking into account the time of

Figure 1. Method of transcription of data from experimentally obtained absorption spectra. The solid line is the absorption spectrum of a solution  $1 \times 10^{-4} M$  in pyridoxal and  $0.1 M$  in DL-alanine at pH 7.0 and  $50^\circ$ . This spectrum was selected as typical of those considered in this paper: O, points at  $5\text{-m}\mu$  intervals between wavelength limits WVL0 and WVL3 whose absorbance values, after any correction for solvent blanks, are transcribed to punched cards; ●, supplemental points added in the wavelength range WVL1-WVL2.

measurement of every point in the spectrum. According to the spectrum, suitable wavelength limits WVL0, WVL1, WVL2, and WVL3 are chosen (Figure 1). WVL0 and WVL3 are lower and upper limits between which absorbance data are collected at  $5.0\text{-m}\mu$  intervals. The spectral peaks of pyridoxal and its derivatives are sharper in the lower wavelength region than at longer wavelengths. To accurately portray the spectra in this lower region, supplemental data near the absorption peaks must be provided. These supplemental data are recorded in the region from WVL1 to WVL2, again at  $5.0\text{-m}\mu$  intervals. Since we define  $WVL1 = WVL0 + 2.5$ , the supplemental data fall at wavelengths halfway between those of the principal set of data (Figure 1). In this work WVL0 is either  $230$  or  $245\text{ m}\mu$ , WVL2 is  $327.5\text{ m}\mu$ , and WVL3 is  $500\text{ m}\mu$ . A total of 69 or 75 points is used.

It is aesthetically desirable to draw a smooth curve between experimental points when plotting a spectral curve. This is done by a two-step interpolation. In the first step, points are computed midway between each pair of experimental points by fitting segments of third-order equations to pass through four consecutive points. At the ends of the spectra, segments of second-order equations are fitted to three points. From this first step of the procedure, points at  $2.5\text{-m}\mu$  intervals are available, half experimental and half interpolated. However, if a supplemental datum was recorded at a particular wavelength, the interpolated value is discarded in favor of the supplemental experimental one. The result of this operation is shown in Figure 2. The open circles on the two curves represent experimental data at  $5.0\text{-m}\mu$  intervals and the closed squares are the interpolated points. It is seen that for curve A, having a moderately sharp curvature, the calculated points fall very close to the true absorption curve, represented by the solid line. In curve B, which contains two very narrow peaks, the calculated points do not lie on the true curve. In this case, supplemental data (open triangles) must be included.

Figure 2. Comparison of interpolation procedure for curves with broad and narrow valleys and peaks. Curves A and B represent assumed experimental curves, —, with the selected data points at  $5\text{-m}\mu$  intervals, O; Δ, supplemental data points, and ■, interpolated points from the first step (see text); ●, interpolated points from the second step.

In the second step, an entirely similar procedure using third-order equations is followed to obtain interpolated values between each pair of points at  $2.5\text{-m}\mu$  intervals. These interpolated points obtained in the second step are indicated by small closed circles in Figure 2B. We now have points at  $1.25\text{-m}\mu$  intervals. The automatic plotter locates these points and draws straight line segments between them to give the final curve.

### Methods of Calculation

**A. Successive Dissociation of Three Protons.** In a compound like pyridoxal hydrochloride there are two readily dissociable protons, and the three ionic forms may be represented as  $H_2P$ ,  $HP$ , and  $P$ . In strongly alkaline solution, a third dissociation occurs. We have designated the resulting form as  $POH$ , but no chemical significance is to be attributed to this symbol. The four ionic forms and three  $K_a$  values may be represented schematically as in eq 1.

The total concentration of all forms of pyridoxal,  $C_{TP}$  (equal to the sum of concentrations of the four individual forms), can be expressed as the product of the concentration of any one of the individual ionic forms and some function of the three  $K_a$  values and the pH (e.g., eq 2 and 3). The symbol  $a_H$  represents the ap-

$$C_{TP} = \alpha C_P \quad (2)$$

$$\alpha = 1 + a_H/K_{2P} + (a_H)^2/(K_{1P}K_{2P}) + K_{3P}/a_H \quad (3)$$

parent hydrogen ion "activity" as represented by the pH meter reading

$$a_H = 10^{-pH} \quad (4)$$

It is assumed that, for dilute solutions, concentrations of all other species may be used in the calculations. Equations 5-7 give the relationships of the concentrations of  $H_2P$ ,  $HP$ , and  $POH$  to that of form  $P$ .

$$C_{H_2P} = (a_H)^2 C_P / (K_{1P}K_{2P}) \quad (5)$$

$$C_{HP} = a_H C_P / K_{2P} \quad (6)$$

$$C_{\text{POH}} = K_{\text{HP}} C_{\text{P}} / a_{\text{H}} \quad (7)$$

**Least-Squares Calculation of Molar Extinction Coefficients of Individual Ionic Species.** If it is assumed the Beer-Lambert law holds for all species, each molar absorptance,  $A$ , may be represented by

$$A = \sum_{j=1}^4 C_j \epsilon_j l \quad (8)$$

$j = 1, 2, 3$ , and  $4$  refer to the four ionic species,  $\text{P}$ ,  $\text{HP}$ , and  $\text{H}_2\text{P}$ , respectively, and  $l$  is the path length. In the remaining treatment,  $l$  is assumed to be 1 cm. At any one wavelength, the  $\epsilon$ 's are constant but the concentrations,  $C_j$ , vary with pH. To obtain the values of  $\epsilon$  at a certain wavelength, we must measure the absorbancies of at least four solutions of different pH and solve a set of simultaneous linear equations.

In general, we obtain data for more than four solutions, and use a least-squares method to obtain the values of the  $\epsilon$ 's. Since we wish to obtain these values at each of the 69 to 75 selected wavelengths, the least-squares procedure is applied consecutively to the data at each wavelength.

The sum of the squares of the deviation,  $U$ , for all solutions at all values of pH and at all wavelengths is given by

$$U = \sum_{ik} \omega_k (A_{ik} - \sum_{j=1}^4 C_j \epsilon_{jk})^2 \quad (9)$$

where the index  $i$  refers to the pH and  $k$  to the wavelength. A weighting factor,  $\omega_k$ , is also introduced, which has been taken as 1.0 at higher wavelengths and as  $\lambda^2$  at wavelengths between WVL0 and WVL2. In the shorter wavelength region twice as many points (many interpolation points per wavelength interval were used in the comparisons), and we wanted to weight the different species equally. Other weighting factors can be used if desired.

The values of the  $\epsilon$ 's corresponding to the minimum value of  $U$  are computed by standard methods. The value of  $U$  is an index of the goodness of fit and plays an important role in the subsequent automatic adjustment of  $pK_a$  values. However, it is not a completely adequate index, because there is a possibility of obtaining the adjustment of  $pK_a$  values, some extinction coefficients for some species will be negative. This became evident in early attempts to fit the data for pyridoxal when the computer moved the values of  $pK_a$  to an incorrectly high value and fitted the data by assuming that the spectrum of POH contained regions of negative absorption.

To diminish the possibility of arriving at a false solution with negative extinction coefficients, a new measure of error,  $U_a$ , was defined

$$U_a = U + \sum_{jik} (C_i \epsilon_{neg})^2 \quad (10)$$

$\sum_{jik} (C_i \epsilon_{neg})^2$  represents the sum of squares of solutions for all negative values of  $\epsilon$ . These latter are weighted heavily in the summation by multiplication by the square of the total pyridoxal concentration,  $C_{\text{TP}}$ . This procedure is rather arbitrary, but to be effective.

**Automatic Adjustment of  $pK_a$  Values.** Two methods have been employed for the adjustment of the values.

**a. Program SWING.** If the successive  $pK_a$  values differ sufficiently, e.g., by about 3 units, each  $pK_a$  can be adjusted independently. The procedure is to first inspect the original spectral data and to estimate within a few tenths of a  $pK$  unit the successive  $pK_a$  values. Of course, the dissociations must lead to a distinctly perceptible change in the spectrum. These trial values of the  $pK_a$ 's are supplied to the computer along with the experimental data. The least-squares calculation of molar extinction coefficients is performed and the sum of squares of deviations,  $U_a$ , is evaluated. Then the first  $pK_a$  is altered by an increment of value,  $\Delta$  (here  $\Delta = 0.4$ ). All computations are repeated and a new value of  $U_a$  is determined and compared with the first one. Depending upon whether the difference between the two values of  $U_a$  is positive, negative, or zero, the  $pK_a$  is varied again, either in the same direction or by  $0.5 \Delta$  in the opposite direction. After about 12 cycles of adjustment and recalculation, the value of  $\Delta$  falls to below 0.004 and the second  $pK_a$  is adjusted next. If any two  $pK_a$  values are close enough together to "overlap," it is necessary to repeat the entire calculation a second or third time to ensure a correct answer.

**b. Program PITMAP.** A second method for dealing with "overlapping" dissociation constants is based on the theory developed by Sillén and Ingri.<sup>4</sup> When some of the adjustable constants have a correlation with others, the shape of the pit made by  $U_a$  in the multidimensional space of  $pK_a$  values becomes so skewed that the direction of the change in constants should be transformed to those of the main axes of the ellipsoid made by the contour lines on the pit surface. Near the minimum point, the shape of the surface is assumed that of a paraboloid in multidimensional space, the equation of which can be established from the values of  $U_a$  for  $0.5(N+1)(N+2)$  systematically chosen points (here,  $N$  represents the number of the constants being searched for). The  $pK_a$  values corresponding to the minimum point on this surface may be computed directly from the equation so obtained. In a future report, the results of application of this method to data for pyridoxamine and other substances with overlapping  $pK_a$ 's will be described. The method was used in the present work only for evaluation of equilibrium constants in the systems containing Schiff's bases.

**3. Standard Deviation.** The standard deviation,  $\sigma$ , of each  $pK_a$  value is given by eq 11 where  $U_{a0}$  is the

$$\sigma = \left( \frac{2U_{a0}}{N_{df} \delta^2 U_a / \delta pK^2} \right)^{1/2} \quad (11)$$

value of  $U_a$  corresponding to the best value of  $pK_a$  which has been found;  $N_{df}$ , the number of degrees of freedom, = (no. of solutions - no. of  $pK_a$  values)  $\times$  (no. of wavelengths used). The standard deviation of the absorbance values is given by eq 12. The value of

$$s = (U_{a0}/N_{df})^{1/2} \quad (12)$$

$\sigma$  is computed by assuming a parabolic form for the variation of  $U_a$  with  $pK_a$  in the range  $\pm 0.01$  of the best value of  $pK_a$  which is found.

**4. Comparison Plots of Calculated and Observed Spectra.** **Program PLOT.** The absorbance of a solution can be expressed as the sum of the contributions of each molecular species present (eq 8). Since the concentrations of individual ionic forms and their extinction

coefficients at all wavelengths have been computed, it is a simple matter, using eq 8, to calculate the expected absorbance at all wavelengths for a solution of any pH. If a pH is selected for which the spectrum has been measured experimentally, the experimental data may be plotted along with the calculated curve. A program has been written that does this. If no experimental data are available at exactly the pH selected, a linear interpolation is made between the data for two nearby pH values. In a similar way, the calculated absorbance at any wavelength may be plotted against pH, together with experimental points. If the selected wavelength is not one represented in the input data, an interpolation with a third-order equation is employed.

**B. Reversible Formation of Schiff's Bases.** The various equilibria of acid dissociation and formation of Schiff's bases in the system pyridoxal-alanine may be represented by the following scheme, which will also be applicable in many other cases.

P represents pyridoxal, L the amino acid, and PL the Schiff's base. The formation constant,  $F_{PL}$ , relates the concentrations of the anions of P and of L to the dianion of PL.<sup>8</sup>

For the system 5-deoxypyridoxal-L-leucine we have proposed additional equilibria leading to formation of a complex of unknown structure between the Schiff's base and the amino acids (eq 17).<sup>9</sup> Four functions,

$\alpha$ ,  $\beta$ ,  $\gamma$ , and  $\eta$ , of the pH and of the acid dissociation constants are introduced.

$$\alpha = 1 + a_{\text{H}}/K_{2P} + (a_{\text{H}})^2/(K_{1P}K_{2P}) + K_{3P}/a_{\text{H}} \quad (18)$$

$$\beta = 1 + a_{\text{H}}/K_{2L} + (a_{\text{H}})^2/(K_{1L}K_{2L}) \quad (19)$$

$$\gamma = 1 + a_{\text{H}}/K_{3PL} + (a_{\text{H}})^2/(K_{2PL}K_{3PL}) + (a_{\text{H}})^3/(K_{1PL}K_{2PL}K_{3PL}) \quad (20)$$

$$\eta = 1 + a_{\text{H}}/K_{3PL2} + (a_{\text{H}})^2/(K_{2PL2}K_{3PL2}) \quad (21)$$

If values for all the constants were known, it would be possible to compute the concentrations of the various species as follows. The total concentrations of pyridoxal ( $C_{\text{TP}}$ ) and amino acid ( $C_{\text{TL}}$ ) for any solution can be expressed by eq 22 and 23. The concentrations of

$$C_{\text{TP}} = \alpha C_{\text{P}} + \gamma C_{\text{PL}} + \eta C_{\text{PL}_2} \quad (22)$$

$$C_{\text{TL}} = \beta C_{\text{L}} + \gamma C_{\text{PL}} + 2\eta C_{\text{PL}_2} \quad (23)$$

Schiff's base ( $C_{\text{PL}}$ ) and of a complex of the latter with

amino acid (if present) ( $C_{\text{PL}_2}$ ) are given by eq 24 and 25 which define the formation constants,  $F_{\text{PL}}$  and  $F_{\text{PL}_2}$ .

$$C_{\text{PL}} = F_{\text{PL}} C_{\text{P}} C_{\text{L}} \quad (24)$$

$$C_{\text{PL}_2} = F_{\text{PL}_2} C_{\text{PL}} C_{\text{L}} \quad (25)$$

The value of  $C_{\text{P}}$  is obtained through successive approximations. If an excess of amino acid is present, the first estimate of  $C_{\text{L}}$  is given by eq 26 and successive estimates of  $C_{\text{P}}$  and  $C_{\text{L}}$  by eq 27 and 28. Concentrations

$$C_{\text{L}} = C_{\text{TL}}/\beta \quad (26)$$

$$C_{\text{P}} = C_{\text{TP}}/[\alpha + (\gamma + \eta F_{\text{PL}_2} C_{\text{L}}) F_{\text{PL}} C_{\text{L}}] \quad (27)$$

$$C_{\text{L}} = C_{\text{TL}}/[\beta + (\gamma + 2\eta F_{\text{PL}_2} C_{\text{L}}) F_{\text{PL}} C_{\text{P}}] \quad (28)$$

of the other three ionic forms of pyridoxal are given by eq 5-7. The concentrations of the various forms of the Schiff's base are given by eq 29-33.

$$C_{\text{H}_3\text{PL}} = (a_{\text{H}})^3 C_{\text{PL}}/(K_{1PL}K_{2PL}K_{3PL}) \quad (29)$$

$$C_{\text{H}_2\text{PL}} = (a_{\text{H}})^2 C_{\text{PL}}/(K_{2PL}K_{3PL}) \quad (30)$$

$$C_{\text{HPL}} = a_{\text{H}} C_{\text{PL}}/K_{3PL} \quad (31)$$

$$C_{\text{H}_2\text{PL}_2} = (a_{\text{H}})^2 C_{\text{PL}_2}/(K_{2PL2}K_{3PL2}) \quad (32)$$

$$C_{\text{HPL}_2} = a_{\text{H}} C_{\text{PL}_2}/K_{3PL2} \quad (33)$$

**1. Molar Extinction Coefficients of Individual Ionic Species.** We assume as before that the Beer-Lambert law holds and that the experimental absorbance for a particular solution and a particular wavelength is given by eq 8 where  $j = 1-11$  designate the eleven ionic species, POH, P, HP, H<sub>2</sub>P, PL, HPL, H<sub>2</sub>PL, H<sub>3</sub>PL, PL<sub>2</sub>, HPL<sub>2</sub>, and H<sub>2</sub>PL<sub>2</sub>, respectively.

Although 11 light-absorbing ionic species are included, these ordinarily will not all be present in significant amounts. In the system pyridoxal-alanine, there is no evidence for the complex HPL<sub>2</sub>, and even in the system 5-deoxypyridoxal-leucine, where HPL<sub>2</sub> is present, the ionic forms H<sub>2</sub>PL<sub>2</sub> and PL<sub>2</sub> exist in such small quantities that they have a very small effect on the over-all spectrum. Their spectra were assumed, for the purposes of computation, to be identical with those of H<sub>2</sub>PL and PL, respectively. Thus, we had to consider only seven of the possible 12 species in either system; for pyridoxal + alanine, POH, P, HP, H<sub>2</sub>P, PL, HPL, and H<sub>2</sub>PL; and for 5-deoxypyridoxal + leucine, P, HP, H<sub>2</sub>P, PL, HPL, H<sub>2</sub>PL, and HPL<sub>2</sub>. Since the  $\epsilon$ 's for POH, P, HP, and H<sub>2</sub>P were already known, extinction coefficients remained unknown for only four species. These were obtained by a least-squares method as described previously. It is usually feasible to evaluate a maximum of four unknown sets of extinction coefficients at once, and depending upon the details of the system under investigation, it may be a different set of four for one system than for another. A program has been written which permits one to state conveniently the appropriate simplifications and to specify which sets of  $\epsilon$ 's (up to four) are to be evaluated.

The error function is defined as in eq 9 except that the second set of terms is multiplied by 100 to discourage strongly the obtaining of false solutions with negative extinction coefficients in some regions.

**2. Adjustment of Values of  $pK_a$  and Log  $F$ .** **1. Program GRID.** In seeking the best values for the  $pK_a$ 's and formation constants we may regard the error func-

(8) D. E. Metzler, *J. Am. Chem. Soc.*, **79**, 485 (1957).

(9) D. E. Metzler and K. Nagano, Proceedings of Second IUB Symposium on Chemical and Biological Aspects of Pyridoxal Catalysis, Moscow, Sept 1966, in press.

,  $U_a$ , as a variable which is dependent upon the trial parameters" (values of the  $pK_a$ 's and  $\log F$ 's). The minimum value of  $U_a$  may be visualized as lying in a multidimensional "pit" in the hypersurface defined by  $U_a$  as a function of the trial parameters. We seek to find the values of the trial parameters at the bottom of the pit. In the systems under consideration there is a strong correlation among the trial values of  $pK_a$  and the two  $pK_{2PL}$ 's,  $pK_{2PL}$  and  $pK_{3PL}$ . Likewise the values of  $F_{PL2}$  and  $pK_{3PL}$  are strongly correlated. Hence the direct method of varying each parameter independently (program SWING) cannot be applied. The simplest approach is to vary each parameter by a certain amount,  $\Delta$ , both in the positive and negative directions and to evaluate  $U_a$  for each of the three important trial values. If this is done for all the parameters and for all possible combinations of the altered values, an  $n$ -dimensional grid of  $3^N$  values of  $U_a$  is obtained, where  $N$  is the number of constants being varied. If  $N = 4$  and we use data for all wavelengths in 30 test solutions, the computation takes almost 10 min and is excessively expensive. It is more practical to vary only three constants at once, the computation amounting to about 4 min.

The results of the computation are inspected to determine which values of the trial parameters gave a minimum  $U_a$ , and three difference values of each parameter are chosen, usually more closely spaced than for the first "grid." The procedure can be repeated as often as the new set of trial parameters gives a smaller value of  $U_a$  than the minimum value obtained previously. For the first grids we have used values of  $\Delta = 0.4$  and for later ones  $\Delta = 0.1$ . Final refinement of the parameters is done with program PITMAP (1b).

**Sequence of Computations.** A workable procedure for the solution of problems of the type considered here is as follows. (1) Initially make spectral measurements on several solutions containing a high concentration of the second component, L, and from an examination of the spectra choose initial trial values for  $pK_a$ 's of PL. Also measure spectra at a constant ionic strength in a region where formation of PL is extensive for the lower concentrations of component L. This will permit the choice of an initial trial value of  $F_{PL}$ . Collect for the initial computations the minimum necessary number of experimental spectra. This number will always be at least as great as the number of unknowns ( $pK_a$ 's,  $\log F$ 's, and spectra of individual ionic forms). (2) Start the computation with the data for the concentrations of amino acid and adjust  $pK_{2PL}$ ,  $pK_{3PL}$ , and  $F_{PL}$  using program GRID and  $\Delta = 0.4$ . (3) Repeat using a grid of  $\Delta = 0.1$ . (4) Use program PITMAP with  $\Delta = 0.01$  which will not only refine the trial parameters but will punch out on cards the spectra of the individual ionic forms of PL which are needed for step 6. (5) Using program PLOT, compare calculated and experimental plots of absorbance against pH and wavelength. If a good fit is obtained, the problem is solved. (6) If systematic errors are detected for different concentrations of amino acid, consider what additional equilibria must be added. The exact procedure can be given for finding the values of the additional equilibrium constants which may be required. The grid method with refinement with program PITMAP in several steps was used in this work.

One must always ask whether the spectra obtained are reasonable from a chemical viewpoint.

## Results

**5-Deoxypyridoxal.** The simplest case studied is that of 5-deoxypyridoxal which exists in three ionic forms. From spectra at 24 values of pH from 1.4 to 12.9, the  $pK_a$  values of 4.16 and 8.02 were evaluated in 118 sec of computation (Table I). The plots comparing computed and observed absorbances show a nearly perfect fit, the standard deviation of the absorbances,  $s$ , amounting to only 0.001 absorbance unit. A few extinction coefficients are given in Table II.

**Pyridoxal.** Pyridoxal exists in solution largely as the internal hemiacetal, four ionic forms of which are shown in Scheme I. Each of these is considered to be in equilibrium with a smaller amount of free aldehyde, the structure of which, H<sub>2</sub>P(a), is drawn only for form H<sub>2</sub>P. The structure assigned to POH is, however, not completely certain.

The first two  $pK_a$  values have been determined previously at 25°. In this study the spectra and  $pK_a$  values have all been measured at 50° because related kinetic studies are being conducted at this temperature.

Spectra were measured for 19 solutions at pH values of 1.03, 3.14, 3.58, 3.91, 4.36, 4.66, 5.60, 6.55, 6.87, 7.52, 7.92, 8.35, 8.65, 9.25, 9.75, 10.16, 12.15, 12.82, and 13.16. No buffers were used, but the pH was adjusted with HCl or KOH. An ionic strength of 1.0 was maintained by addition of KCl. Figure 3 shows the spectra of the four ionic forms. That of form POH is presented for the first time. Figures 4 and 5 show plots of calculated and observed spectra at two selected pH values and spectrophotometric titration curves at three selected wavelengths as drawn by the automatic plotter. The agreement is good, even at the highest

Scheme I

pH. The  $pK_a$ 's are given in Table I and extinction coefficients at the maxima in Table II.

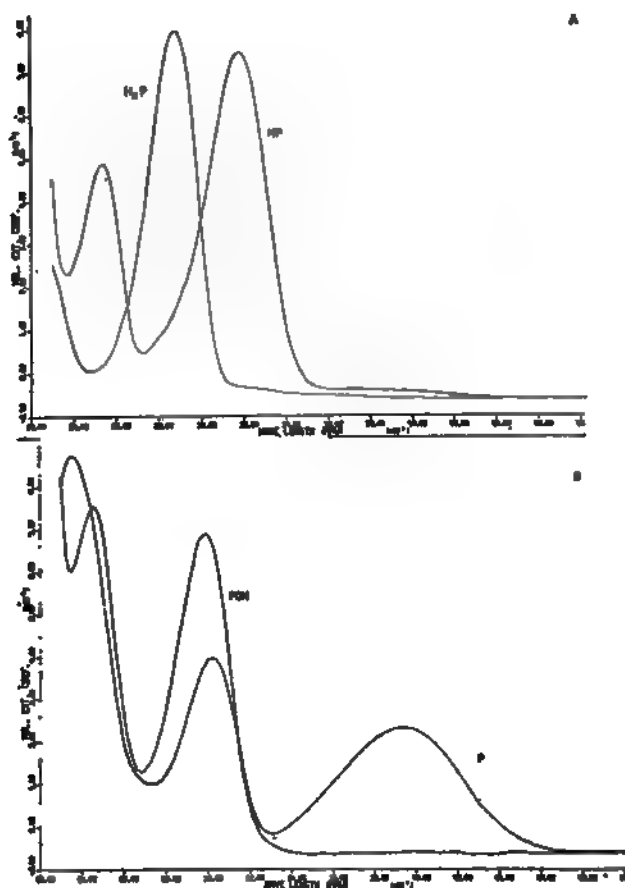

Figure 3. Absorption spectra of the four ionic forms of pyridoxal at 50°C: graph A,  $\text{H}_3\text{P}$  and  $\text{HP}$ ; graph B,  $\text{P}$  and  $\text{POH}$ .

**Pyridoxylidene-DL-alanine.** This Schiff's base, formed from the rapid, reversible reaction of alanine with pyridoxal, exists in the three ionic forms  $\text{H}_2\text{PL}$ ,  $\text{HPL}$ , and  $\text{PL}$  whose probable structures are shown below.

Figure 4. Calculated absorption spectra of solutions of  $10^{-4} M$  pyridoxal at two pH values plotted together with experimental points, temperature 50°C:  $\Delta$ , pH 4.36;  $\circ$ , pH 13.16.

Figure 5. Plots of absorbance vs. pH at selected wavelengths for a  $10^{-4} M$  solution of pyridoxal at 50°C: +, 394  $m\mu$ ;  $\Delta$ , 318  $m\mu$ ;  $\circ$ , 288  $m\mu$ .

The formation and acid dissociation constants are given in Table III, and the spectra of the three ionic species are shown in Figure 6 and in Table IV. These were evaluated from data for a total of 45 experimental solu-

tions of pyridoxal concentration  $10^{-4} M$  and alanine concentrations from 0.05 to 0.45  $M$  (see Experimental Section). The comparison plots of observed vs. computed spectra, of which those in Figures 7-9 are typical, were all reasonably satisfactory. Figure 7 shows spectra at three values of pH for solutions 0.1  $M$  in alanine and  $10^{-4} M$  in pyridoxal, while the pH profiles in Figures 8 and 9 are for solutions 0.05 and 0.45  $M$  in alanine, respectively, and  $10^{-4} M$  in pyridoxal. The existence of forms containing more than one molecule of pyridoxal,

Figure 6. Absorption spectra of the three ionic forms of pyridoxylidene-DL-alanine at 50°. The unevenness of the spectrum of  $H_2PL$  results from the fact that this form exists in very small amounts so that experimental errors lead to uncertainty in the spectrum, especially at the lower wavelengths.

Figure 8. Plots of absorbance *vs.* pH at selected wavelengths for a  $10^{-4}$  M solution of pyridoxal containing 0.05 M DL-alanine at 50°: +, 420 mμ; Δ, 3.75 mμ; O, 302.5 mμ.

Figure 7. Calculated absorption spectra for solutions of  $10^{-4}$  M pyridoxal containing 0.2 M alanine at three values of pH plotted together with experimental points, temperature 50°: +, pH 4.53; Δ, pH 8.40; O, pH 11.11.

Figure 9. Plots of absorbance *vs.* pH at selected wavelengths for a  $10^{-4}$  M solution of pyridoxal containing 0.449 M alanine at 50°: +, 420 mμ; Δ, 365 mμ; O, 285 mμ.

*e.g.*,  $P_2L_2$ , was ruled out by measurement of 18 solutions containing 100 times higher concentrations of pyridoxal and 0.45 M alanine using spacers in the spectrophotometer cells to cut the path length. Calculated and observed spectra agreed equally satisfactorily for these solutions. The standard deviation, *s*, was 0.013 absorbance unit.

**5-Deoxypyridoxylidene-L-leucine.** Results for the system 5-deoxypyridoxal-L-leucine, at 25°, have been reported briefly elsewhere<sup>9</sup> and will be summarized

Figure 10. Plot of the computed pH profile of concentrations of free pyridoxal (all forms),  $H_2PL$  (multiplied by 100),  $H_2PL$ , HPL, and PL for solutions of  $10^{-4} M$  pyridoxal containing  $0.449 M$  DL-alanine, —, and  $0.05 M$  DL-alanine, ----, at  $50^\circ$ . The concentration of  $H_2PL$  was computed on the assumption that  $pK_{PL1} = 2.5$ , the same as that of alanine. Of course the true value of this  $pK$  might be quite different and the fit would still be good.

here. This system is a favorable one for study because of the high degree of formation of the Schiff's base over a broad range of pH. Initially it was assumed that the three forms of the Schiff's base,  $H_2PL$ , HPL, and PL, were the only forms present and the equilibrium constants were obtained from the data for solutions containing  $0.05$  and  $0.1 M$  leucine. However, the spectra of solutions containing  $0.01 M$  L-leucine could not be predicted accurately using these constants. Introduction of a complex,  $HPL_2$ , resolved the difficulty. This was found to have a spectrum nearly identical with that of HPL and apparently is a complex of the latter species with the anion of L-leucine. The spectra are shown elsewhere<sup>9</sup> and only the constants are given in Table III. The spectrum of HPL is very similar to that reported previously for pyridoxylidene-DL-valine<sup>8</sup> while that of PL is surprisingly different, possessing an absorption maximum at  $343 m\mu$ . The precise spectrum of  $H_2PL$  was obtained. It absorbs maximally at  $414 m\mu$  and possesses a higher molar extinction coefficient than does HPL.

In considering various problems of equilibria and kinetics, it is useful to know the concentration of each ionic form present at a particular pH. These pH profiles may be computed readily using the auxiliary program designated PROFILE. Figure 10 shows the results of such a program for the pyridoxal-DL-alanine system and alanine concentrations of both  $0.449$  and  $0.1 M$ . This program also computes another useful function, the pH-dependent apparent formation constant which has been designated previously as  $K_{pH}$ <sup>8</sup> (eq 34). The

$$K_{pH} = \gamma C_{PL} / \alpha C_P \beta C_L \quad (34)$$

term  $\alpha C_P$  represents the total of all free forms of pyridoxal, etc. In Figure 11 a plot of  $\log K_{pH}$  vs. pH is shown for both the pyridoxal-alanine and deoxypyridoxal-leucine systems.

## Discussion

The methods described here permit the automatic evaluation of from one to three successive acid dissociation constants for compounds for which each ionic

Figure 11. Plots of the logarithm of the apparent formation constant ( $K_{pH}$ ) vs. pH for 5-deoxypyridoxylidene-L-leucine at  $25^\circ$  and for pyridoxylidene-DL-alanine at  $50^\circ$ .

form possesses a substantially different spectrum, the rapid evaluation of formation constants and acid dissociation constants of complexes or compounds formed reversibly in the presence of a second nonlight-absorbing component, and plotting of complete absorption spectra of all ionic species which contribute significantly to the absorption of light. They should have widespread use. The advantages of this method for obtaining dissociation constants are: (1) a least-squares method assures the best values for dissociation constants and extinction coefficients of individual ionic forms at all wavelengths. (2) The method is rapid. (3) Precise spectra of intermediate ionic forms are provided, whereas previously tedious calculation was often required. (4) A large number of plots of the type displayed in Figures 4, 5, 7, 8, and 9 may be obtained readily and inexpensively. These permit a visual judgement of goodness of fit and show at a glance at what wavelengths and under what conditions of pH, concentration, etc., discrepancies exist. (5) Data for  $pK_a$ 's and extinction coefficients of individual ionic forms are stored on punched cards or by other means in digital form. The data are thus immediately available for use in calculations of chemical equilibria and kinetics in more complex systems.

The method of evaluation of formation constants is superior to the widely used procedure of Ketelaar, *et al.*,<sup>10</sup> because (1) it uses data at many different wavelengths, (2) it yields  $pK_a$  values for the compound or complex when its absorption spectrum is altered by association or dissociation of protons, (3) complete absorption spectra of the various forms of the compound or complex are computed, (4) a series of comparison graphs showing experimental data plotted with the computed curves provide a means of judging directly the goodness of fit, and (5) the chemical model can be varied easily, *e.g.*, by introducing additional equilibria, and can readily be tested to determine whether a better fit is obtained. The method can be applied directly to many chemical and biochemical problems including study of enzyme-substrate complexes and can be used to advantage in handling various kinetic problems as will be discussed in a future paper. The

ach should be of value in various problems of complex formation.<sup>11</sup>

transcription of data points by hand from experimental graphs used in this study is tedious and often to introduction of errors, the most serious of which must be traced and removed before acceptable results are obtained. However, with the computer programs available, the many users of recording spectrophotometers may immediately employ these methods. A more desirable system will be to collect data directly in digital form, and equipment for doing this is readily available commercially. Doubtless, within a few years older methods of handling spectrophotometric data will be completely obsolete. An important advantage of the newer methods will be that complete experimental data can be sent between laboratories over telephone wires. Thus a much more efficient sharing of information will be available.

During the course of this study many questions have arisen for which full answers are not yet available. For example, "How great must be the differences between the spectra of two successive ionic forms in order to justify the evaluation of the  $pK_a$ 's?" It is clear that each ionizable group must affect the spectrum. Thus, if a compound possesses two groups of identical microconstants, but the dissociation of one group has no effect on the spectrum, the two step-dissociation constants of the compound cannot be determined from spectral data alone. In such cases both spectra and titration data are required.

It is necessary in our method to provide to the computer an initial estimate for each  $pK_a$ . If all of the  $pK_a$ 's are well separated it is easy to do this by inspection of the data. Even if the initial guess is poor, both programs SWING and PITMAP lead to a rapid selection of the correct value. However, if the  $pK_a$  values are close, difficulties may be anticipated, especially if several initial guesses are made. We are investigating the merits of this type.

An important question is "What is the minimum number of experimental spectra which must be measured in order to obtain precise answers?" It appears that no more than the minimum which are theoretically required (for the determination of  $pK_a$ 's, three for the first  $pK_a$  and two for each successive  $pK_a$ ) are needed, but at a few more are to be recommended. In general, the usual "common sense" judgement of the chemist regarding the number and distribution of pH values for samples should be followed.

Another question concerns the treatment of experimental errors. Errors in the spectra may vary with the wavelength, being higher where the slope of the spectral curve is steep. Accordingly, it would be desirable to use the weighting factors,  $w_\lambda$ , with the wavelength for each solution. However, this has not been done in this study. The standard deviations in the  $pK_a$ 's are very low (Table I) and are considerably less than what we would judge to be the experimental error in the measurements. However, the standard error is properly evaluated and represents a useful index of the reproducibility of the computations. The standard deviation of the absorbances,  $s$  (eq 12), represents an average value for all wavelengths and all solutions and does

not indicate whether systematic errors exist in certain regions of wavelength or pH. That such systematic errors do exist for some solutions is obvious from inspection of comparison plots of the type of Figures 4 and 7. If the experimental pH is near a  $pK_a$  value, a small error in pH will lead to large systematic deviations, even though the value of  $s$  may be acceptably small. The careful examination of a series of plots of the type of Figures 4, 5, 7, 8, and 9 is extremely valuable in deciding whether observed systematic deviations are within acceptable limits as set, for example, by the precision of pH measurement or whether the assumed chemical model is inadequate.

A particular problem in the evaluation of  $pK_a$ 's arises when incomplete data are available for a dissociation step. Pyridoxal is an excellent example. No data were obtained above pH 13.16, but  $pK_{1,2}$  is 13.0. As was mentioned earlier, before steps were taken to discourage the assignment of negative extinction coefficients, the computer preferred to assign a higher value of  $pK_{1,2}$  and negative extinction coefficients to POH in the region around 390 m $\mu$ . But what is the possibility that the true solution is for a  $pK_{1,2}$  value lower than 13.0 and higher extinction coefficients for POH around 390 m $\mu$ ? An acceptable but less perfect fit to the data could be obtained by letting  $pK_{1,2}$  be as low as 12.74. However, the computed spectrum of POH in this case possessed another absorption band at 390 m $\mu$  with  $\epsilon$   $0.8 \times 10^3$  (27% of that of P), a result which seems very unlikely on chemical grounds.

Information on spectra and  $pK$  values is now available for a small number of different Schiff's bases.<sup>8,12</sup> For all of these the spectrum of form HPL is similar, but striking differences are observed in the spectrum of form PL and in the  $pK$  for dissociation of HPL to PL. The basic causes of these differences are not understood, but we believe that the study of other analogs of pyridoxal and of other amino acids will give information which will permit us to understand these variations and to interpret them in the light of possible significance to the events which take place on a surface of enzymes which employ pyridoxal phosphate as a coenzyme.

## Experimental Section

**Chemicals.** Pyridoxal·HCl (Sigma Chemical Co.), DL-alanine (Nutritional Biochemicals Corp.), and L-leucine (methionine-free, Mann Research Laboratories, Inc.) were used without further purification. 5-Deoxypyridoxal was synthesized by Dr. C. Iwata in this laboratory.

**Measurements of pH.** A Beckman Model G pH meter was used. Commercially available standard buffer solutions (Beckman Instruments, Mallinckrodt Chemical Works, or Matheson Coleman and Bell) were used, but later the high pH buffers were replaced by the National Bureau of Standards 0.01 M borax buffer of pH 9.18 at 25° and 9.01 at 50°. All pH values below 12 were determined at 50° by setting the temperature compensator at 25° and standardizing with the dial set at a reading of  $100/100$  times the pH of the standard buffer at 50°. The meter reading for the unknown sample was then multiplied by  $100/100$ . When the pH exceeded 12, the temperature compensator had to be set at 40° (its upper limit) in order to keep the high pH readings on the scale. The meter was adjusted so that the test solutions could be read on the scale. Two pH standards (phosphate at pH 6.83 and borax at pH 9.01) were read at the same temperature and the pH of the test sample was established by a linear extrapolation.

**Test Solutions.** Pyridoxal was studied in unbuffered solutions of ionic strength 1.0. The pH and ionic strength were maintained by addition of suitable amounts of KCl, HCl, and KOH. Deoxy-pyridoxal was studied in buffered solutions of ionic strength 0.1.

Stock solutions of  $2 \times 10^{-4}$  M pyridoxal-HCl and 5-deoxypyridoxal were prepared. They could be stored for a month in a refrigerator without any noticeable change in spectrum. Sample solutions were prepared before measurement by mixing 10 ml of the stock solution of the vitamin B<sub>6</sub> derivative with a 10-ml aliquot of a suitable buffer solution or with the appropriate amount of HCl, or KOH and KCl.

Mixtures of pyridoxal and DL-alanine were studied in unbuffered solutions of ionic strength 1.0 in order to avoid the effects of buffers on the reaction rates which are also under investigation. The pH and ionic strength were maintained by addition of suitable amounts of KCl, HCl, and KOH. Stock solutions of various concentrations of DL-alanine (0.1, 0.2, 0.4, and 0.898 M of ionic strength 2.0) were prepared. Sample solutions were prepared before measurement by mixing 10 ml of the stock solution of pyridoxal maintained at 50° with a 10-ml aliquot of a suitable alanine solution maintained at 50°.

Spectra were obtained for 45 different solutions (eight for 0.05 M alanine, five for 0.1 M alanine, 17 for 0.2 M alanine, and 15 for 0.449 M alanine) in the absence of any special buffers at an ionic strength of 1.0. The measured pH values were: 4.13, 4.52, 5.41, 5.92, 6.73, 7.09, 7.57, 8.18, 8.62, 9.13, 9.53, 10.29, 11.21, 11.71, and 12.83 for 0.449 M alanine; 4.53, 5.00, 5.35, 5.57, 6.55, 7.05, 7.47, 7.95, 8.40, 8.69, 9.21, 9.23, 9.48, 10.24, 11.11, 12.08, and 13.07 for 0.2 M alanine; 7.00, 7.95, 8.61, 12.30, and 13.16 for 0.1 M alanine; and 7.66, 8.28, 9.04, 9.87, 10.82, 11.62, 12.45 and 13.10 for 0.05 M alanine solutions. The sum of squares of the deviations,  $U_n$ , for 45 solutions was 0.50.

The interaction of 5-deoxypyridoxal with L-leucine was studied in buffered solutions of ionic strength 0.1 except at very high pH where the ionic strength exceeded 0.1. Stock solutions of  $3 \times 10^{-4}$  M 5-deoxypyridoxal and of various concentrations of L-leucine (0.015, 0.075, and 0.15 M of ionic strength 0.15) were prepared. Sample solutions were prepared by mixing 10 ml of the stock solution of 5-deoxypyridoxal with a 20-ml aliquot of a suitable buffered leucine solution. Spectra were determined for 39 different solutions (13 for 0.01 M L-leucine, ten for 0.05 M L-leucine, and 16 for 0.1 M L-leucine) in the presence of the indicated buffers at an ionic strength of 0.1. The measured pH values were: 3.28, 4.12, 4.40, 4.62, 5.91 (acetate buffers), 7.33, 7.62, 8.83, 9.59,

10.59, 11.00, 11.27 (potassium carbonate buffers), 11.70, 12.62, 12.99 (KOH) for 0.1 M L-leucine; 3.34, 4.85, 6.17 (acetate buffers), 7.91, 9.81, 10.79, 11.00 (potassium carbonate buffers), 11.71, 12.23, 12.71 (KOH) for 0.05 M L-leucine; 5.98, 6.41, 7.09, 7.70, 8.18 (potassium phosphate buffers), 8.69, 9.13, 10.01, 10.30, 10.80, 11.08 (potassium carbonate buffers) for 0.1 M L-leucine solutions. The sum of squares of deviations for 39 solutions was 0.28, which means that the fitness of the calculated spectra to the observed is excellent.

**Titration of DL-Alanine.** Titration of DL-alanine was at 50° using a Radiometer Model TTT1 automatic pH titrator. 50 ml of 0.02 M DL-alanine solution containing 0.02 N HCl and 0.98 M KCl was prepared. The solution (10 ml) was titrated with 1.0 N NaOH solution which was prepared from 50% aqueous solution of analytical grade NaOH and kept in a polyethylene bottle. The data were treated by our own computer program to give the following  $pK_a$  values:  $pK_{a1} = 2.54 \pm 0.008$  and  $pK_{a2} = 9.014$ .

**Spectra.** All measurements were made with a Cary Model 14 recording spectrophotometer with a thermostated cell holder and a scanning rate of 71 mμ/min. The temperature of the solution in the cuvette was measured by use of VECO Model 41A7 thermometer (Victory Engineering Corp.) and associated galvanometric apparatus. Absorbances were read from the charts to the third decimal place and were entered on 80-column FORTRAN coding form for transfer to punched cards at the computation center.

**Computational Programs.** Programs are written in the language of FORTRAN IV for use with the IBM 360-50 computer. The autographing was done by use of the IBM 1627 (Cal-Comp) incremental plotter. Complete programs are available upon request.

**Acknowledgments.** The authors are indebted to Mrs. M. Nagano for making most of the experimental measurements, to Dr. C. Iwata for the preparation of the 5-deoxypyridoxal, to Drs. H. Jespersen, G. Scrafford, N. Hutton, and other members of the staff of the State University Computation Center, to Drs. Kudo, John Foss, and Jon Applequist, and Mr. R. Johnson for advice in the writing of the manuscript.

# The Crystal and Molecular Structure of 7 $\alpha$ -(1-(*R*)-Hydroxy-1-methylbutyl)-6,14-*endo*-ethenotetrahydrothebaine Hydrobromide (19-Propylthevinol Hydrobromide)

J. H. van den Hende and N. R. Nelson

Contribution from the Organic Chemical Research Section, Lederle Laboratories, A Division of American Cyanamid Company, Pearl River, New York 10965.  
Received December 7, 1966

**Abstract:** The crystal structure of the hydrobromide salt of a Diels–Alder adduct derivative of thebaine (19-propylthevinol) has been determined *via* the phase-determining heavy-atom method. The crystals, which are orthorhombic with the space group  $P2_12_12_1$ , have the unit cell dimensions  $a = 10.60$ ,  $b = 22.34$ , and  $c = 10.14$  Å. Calculation of a three-dimensional Patterson function, followed by several cycles of electron density and finally least-squares refinement, yielded the complete structure. Both the relative configuration at  $C_{11}$  and the absolute configuration of the molecule as a whole were established, the latter *via* anomalous scattering techniques, and the assignments made previously by Kalvoda, *et al.*, for the morphine series were confirmed. The molecular shape, which is partly defined by a complex cage structure, is severely distorted when compared with an idealized Dreiding model. An observed intramolecular hydrogen bond suggests a favored  $sp^3$  rather than  $sp^2$  hybridization for an ether oxygen atom. Accurate bond lengths and valency angles have been obtained and all the protons associated with the rigid molecular framework have been located, including the quaternizing proton, which is in close proximity to a bromide anion.

has been reported by Bentley and Hardy<sup>1</sup> that the preparation of compounds more rigid and complex than morphine could lead to physiologically active substances at least as effective as analgesics as morphine, not exhibiting its unwanted side effects. A series of such compounds, ready access to which was provided by the Diels–Alder addition of dienophiles to thebaine, has been studied in these laboratories and its interesting chemistry reported.<sup>2</sup>

In view of the fact that prior knowledge of the detailed molecular structure of the morphine alkaloids obtained *via* X-ray crystallographic analysis had been limited, it was considered to be imperative to undertake a comprehensive study of at least one of these compounds. Thus, certain aspects of the molecular geometry would be established and a relationship might be obtained between the more subtle structure details and observed physical characteristics.

## Experimental Section

The preparation of the compound which was chosen for this work has been reported by Bentley, *et al.*<sup>3</sup> 19-Propylthevinol (I) is the 1-(*R*)-hydroxy-1-methylbutyl-*r*-carbinol obtained from 7 $\alpha$ -methyl-6,7,8,14-tetrahydro-6,14-*endo*-ethenotetrahydrothebaine by treatment with propylmagnesium iodide.

Single crystals<sup>4</sup> of 19-propylthevinol·HBr were obtained in various sizes by slow crystallization from an aqueous ethanolic solution to which an equivalent of HBr was added. Oscillation, Weissenberg, and precession photographic work established the crystals as orthorhombic, with the unit cell lattice constants  $a = 10.60$  Å,  $b = 22.34$  Å, and  $c = 10.14$  Å. The space group is  $P2_12_12_1$ , which assignment was made due to the absence of all reflections of the  $h00$ ,  $0k0$ , and  $00l$  for which  $h$ ,  $k$ , or  $l$  are odd. The cell constants as obtained with film techniques were confirmed using a XRD-6 diffractometer equipped with a Eulerian cradle. The measured density, 1.383 g/cc, is in good agreement with the calculated value of 1.397 g/cc for a cell content of four molecules of  $C_{21}H_{27}NO_4 \cdot HBr$ .

A specimen of approximate dimensions of  $200 \times 100 \times 60$   $\mu$  was chosen for the intensity data collection after inspection under polarized light and additional photographic fingerprinting had shown it to be a single crystal. Its mosaic spread was found to vary from  $0.4$  to  $0.6^\circ$  and three-dimensional intensity data were taken for those reflections present in the octant with the least variation. Cu  $K\alpha$  radiation was used, with a divergent incident beam, with the stationary counter–stationary crystal technique. Balanced Co and Ni filters were used throughout, and the take-off angle of the X-ray tube was  $2.2^\circ$ . A preliminary investigation had shown the peak widths to vary only slightly, from  $0.5^\circ$  at low scattering angles to about  $1.0^\circ$  at  $2\theta$  values of  $100^\circ$ . The photographic work had shown that all diffraction was limited to the reflections accessible within a sphere determined by this range. During the course of the data gathering several reflections were monitored as a means for observation of possible decay and/or misalignment of the crystal. No decomposition could be detected.

In all, 1772 independent reflections were monitored, of which 516 were deemed to be too weak to be measurable with sufficient accuracy, since they exhibited a count rate smaller than twice that of the background.

Even though the linear absorption coefficient ( $\mu_r = 28.0$ ) indicated that absorption corrections were unnecessary, a systematic variation of the count rate of the polar reflections ( $00l$ ) upon rotation of  $\varphi$  was observed and was attributed to the noncylindrical shape of the crystal and the corresponding difference in the X-ray path lengths. A  $\varphi$ -dependent correction was therefore applied in the subsequent data reduction, which also included the conventional Lorentz and polarization corrections.

The crystal structure was elucidated by the phase-determining heavy-atom method.<sup>4</sup>

A three-dimensional Patterson function  $P(u, v, w)$  was computed with the input data,  $|F|^2$ , sharpened with a coefficient  $(Z_{Br}^2/f_{Br}^2 \exp[2B(\sin \theta/\lambda)^2])$ , where  $Z_{Br}$  is the atomic number of bromine,  $f_{Br}$  the scattering amplitude of a bromide ion at rest at a Bragg angle  $\theta$ , and  $B$  is an over-all temperature factor, which was taken to be  $2.5$  Å<sup>2</sup>. Perusal of the Harker sections at  $u, v$ , and  $w = 1/2$  led at once to the deduction of coordinates for the bromide ions. Assignment of phases based on the calculated contributions of these ions and a subsequent Fourier synthesis ( $\rho(1)$ ) led to the location of 11 additional atomic sites, six of which seemed to form a ring system. Refinement of the phases by the inclusion of the additional atoms followed by a second density map calculation ( $\rho(2)$ ) yielded 11 more atoms, of which one was latter found to be incorrectly placed. A third cycle of Fourier refinement revealed

<sup>1</sup>) K. W. Bentley and D. G. Hardy, *Proc. Chem. Soc.*, 220 (1963).

Figure 1. Final three-dimensional electron-density distribution shown by means of superimposed contour sections drawn parallel to (001) through the calculated atomic centers. Contour intervals  $1.5 \text{ eA}^{-3}$ , except around the bromide ion, where it is  $7 \text{ eA}^{-3}$ .

the complete structure. The average difference between the observed and calculated form factors at this stage was 28%. Two cycles of isotropic block-diagonal least-squares refinement afforded a drop in  $R$  to 0.18 but it was observed that several of the atoms showed large temperature factors, thus placing doubt as to their actual location. A fourth density map ( $\rho(4)$ ) was calculated, omitting these atoms from the phase calculations. This led to the repositioning of two of the atoms (the methyl group on  $C_{18}$  and  $C_1$  of the phenyl ring), but the three other peaks returned in the previously assigned positions. Refinement of the light atoms, which were given individual isotropic temperature factors, while the bromide ions were allowed to vibrate in an anisotropic fashion, led in three more cycles of block-diagonal refinement to an  $R$  value of 0.086. Two cycles of anisotropic refinement of the lighter atoms then yielded an  $R$  of 0.078.<sup>4</sup> At this stage it was found that the parameter shifts were insignificant compared to the calculated standard deviations, and therefore the refinement was terminated.<sup>5</sup> The value of  $R$  including all unobserved reflections as  $0.5F_{\text{min}}$  was 0.12.<sup>7</sup>

A composite final electron density map was evaluated and an area covering one molecule is shown in Figure 1 which contains superimposed sections taken through the centers of the atoms, and is drawn in a direction parallel to (001). The corresponding atomic arrangement is explained in Figure 2. The coordinates and thermal parameters obtained are given in Tables I and II and their standard deviations in Table III. The latter were determined from the least-squares residuals by application of the equation<sup>8</sup>

$$\sigma^2(x_i) = \sum_j w_j (\Delta F_j)^2 / [(n - s) \sum_j w_j (\delta F_j / \delta x_i)^2]$$

(5) The theoretical atomic scattering factors for carbon, nitrogen, oxygen, and bromine used in all the structure factor calculations were taken from the "International Tables for X-Ray Crystallography," Vol. III, The Kynoch Press, Birmingham, 1962, where bromine was corrected for anomalous dispersion. All calculations were carried out on an IBM 7094 digital computer at the ITT Data Processing Center, Paramus, N. J. The Fourier program used was that of Sly-Shoemaker-van den Hende; the least-squares, distance, and other peripheral calculations were carried out using our own programs.

(6) The weighting of the contributions of the individual reflections to the residuals was based on the following scheme: for reflections with  $|F| > 10F_{\text{min}}$  the weight  $w$  was given by  $w = 10F_{\text{min}}/|F|$ , for  $4F_{\text{min}} < |F| < 10F_{\text{min}}$ ,  $w = 10$ , and for  $|F| < 4F_{\text{min}}$ ,  $w = |F|/4F_{\text{min}}$ .

(7) A table with the final values of  $F_o$  and  $F_c$  and the phase angles  $\alpha$  has been deposited as Document No. 9371 with the ADI Auxiliary Publications Project, Photoduplication Service, Library of Congress, Washington, D. C. 20540. A copy may be secured by citing the document number and by remitting \$2.50 for photoprints, or \$1.75 for 35-mm microfilm. Advance payment is required. ### Discussion of the Structure

The spatial configuration of the molecule of 19-propylthevinol, as shown in projection in Figure 2, in many ways resembles that of codeine and morphine, as described by Lindsey and Barnes<sup>9</sup> and by Mackay and Hodgkin.<sup>10</sup>

Since both of these previous analyses were performed with two-dimensional intensity data, we feel compelled to describe the molecular geometry of I with some detail.

Moreover, the absolute configuration of the morphinoids had not been confirmed previously by X-ray analysis even though the elegant chemical work of Kalvoda, *et al.*,<sup>11</sup> leaves little doubt as to its being well established.

The average sp<sup>3</sup>-carbon-sp<sup>3</sup>-carbon single bond length, of 1.543 Å (Table IV), and the average bond length in the aromatic A ring, 1.392 Å, as well as the sp<sup>2</sup>-carbon-sp<sup>2</sup>-carbon length of 1.335 Å, do not differ significantly from expected values.<sup>12</sup>

**Table IV.** Table of Interatomic Distances

**Figure 2.** The atomic arrangement corresponding to Figure 1.

The carbon-nitrogen single bonds, which average 1.516 Å, are longer than expected, however, while the carbon-oxygen bond lengths are in the normal range.

The lengths of the bonds around the atom labeled Pr<sub>1</sub> are quite anomalous, and there is no satisfactory chemical explanation for this effect. We therefore consider it possible that the Pr<sub>1</sub> carbon atom has been misplaced by about 0.1 Å by the least-squares refinement procedure.

A comparison of the results with an idealized Dreiding model shows that the molecule is subject to considerable distortion. The phenyl ring itself is flat, but it can readily be understood that the spacial requirements of the complex cage structure connected to it explain why the connecting bonds (C<sub>4</sub>-O<sub>4</sub>, C<sub>17</sub>-C<sub>13</sub>, and C<sub>11</sub>-C<sub>10</sub>) are not coplanar with the six phenyl carbons.

As is usually observed in methyl phenyl ethers, the 3-methoxyl carbon atom does not lie in the phenyl carbon plane. The five-membered oxygen-containing ring is planar and the piperidyl system is in the chair conformation with the N-methyl equatorial.

In the bicyclo[2.2.2]octene cage, the carbon atoms 17 and 18 are the ones originally present and labeled as C<sub>8</sub> and C<sub>7</sub> in the morphinoids. The ring C<sub>6</sub>-C<sub>7</sub>-C<sub>18</sub>-C<sub>17</sub>-C<sub>14</sub>-C<sub>13</sub> has, because of the added C<sub>7</sub>-C<sub>8</sub> bridge, a different conformation than in morphine, where it is found as a pseudo chair.

As a result of this analysis the conformation at C<sub>19</sub> has been established. The hydroxyl oxygen, O<sub>19</sub>, is coplanar with O<sub>6</sub>, C<sub>6</sub>, and C<sub>19</sub>, and the methyl group, Me<sub>19</sub>, is oriented toward the morphine ethenyl bridge. This result is in agreement with stereochemical considerations of the Grignard coupling which was carried out at C<sub>19</sub> in the preparation of I, since it is reasonable to assume that the MgI ion would preferably interact with both the C<sub>19</sub> and C<sub>6</sub> oxygen atoms in the Grignard complex.

The 19-hydroxyl group forms an intramolecular hydrogen bond with the ether oxygen O<sub>6</sub>. The 6-methyl group is located in such a manner as to facilitate this bonding with the free pairs of O electrons. The O-O distance is 2.63 Å, and the position of the proton, which was located from a difference density map calculation (Figure 3), indicates a O-H...O hydrogen bond angle of 111.2°, with H-O<sub>19</sub> and H-O<sub>6</sub> distances of 1.05 Å and 1.79 Å, respectively. The location of the hydroxyl proton, which is virtually coplanar with the C<sub>6</sub>-O<sub>6</sub>-Me atoms, seems to indicate that the ether

Figure 3. Hydrogen atom positions as obtained from  $F_o - F_c$  synthesis. Contours drawn represent 0.1 electron/Å<sup>3</sup>.

oxygen has an unshared pair of electrons emanating from the atomic center in the same plane as the bonded electrons. This implies that the oxygen atom is not an  $sp^3$  hybrid, but rather that it is  $sp^2$ , trigonal. This is supported by the  $C_6-O_5-Me_4$  valence angle of  $120^\circ$ . In view of this it should also be observed that the angle  $C_7-O_5-Me_3$ ,  $117^\circ$ , is close to the ideal trigonal value of  $120^\circ$ .

The closest nonbonded intramolecular distances are given in Table V, and Table VI is a list of valency bond

allow it some "breathing space." The results are consistent with the nmr and infrared spectral data.<sup>18</sup>

The bromide ions are located in such a manner that a very strong interaction exists with the basic nitrogen of the piperidyl ring. The quaternizing N-proton is directed from the nitrogen in the general direction of a single bromide anion, with the short  $N \cdots Br$  approach distance of 3.17 Å. The  $N-H \cdots Br$  ionic bond angle is  $107^\circ$  with  $N-H$  and  $H \cdots Br$  distances of 1.08 and 3 Å, respectively. The errors in the bond distances are estimated at  $\pm 0.02$  Å, and those in the valency angles as  $\pm 3^\circ$ .

All other short intermolecular distances seem to give rise to only the expected van der Waals contacts (see Table VII). Apart from the above described van der Waals bonding and the ionic  $N-H \cdots Br$  interactions no strong intermolecular forces seem to hold the lattice together. This may explain the relatively high thermal stability which is ascribed to the terminal atoms of the functional groups.

### Absolute Configuration Determination

The absolute configuration was established using the anomalous dispersion of the bromide ions, which causes reflections  $(h, k, l)$  and  $(\bar{h}, \bar{k}, \bar{l})$  to be different in both phase and scattering amplitude, in violation of Friedel's law. Two methods were used: first, the more obvious one in which the structure was refined first with observed crystal planes assigned as  $(hkl)$  and then as  $(h, -k, -l)$ . Even though no dramatic difference in overall  $R$  was observed (0.078 and 0.084, respectively) a complete review of the data showed that for most of the reflections no large changes were calculated, but that

some showed dramatic differences between  $F_o(hkl)$  and  $F_o(-h, -k, -l)$ . For all reflections where this difference was more than 10% in  $|F_o|$  it was obvious that the hand originally chosen was the correct one; for these planes  $R(+++)$  and  $R(---)$  were 0.107 and 0.152, respectively. In order to confirm this result the intensities of the  $(-h, -k, -l)$  reflections were measured.<sup>14</sup> The data are shown in Table VIII, and they confirm the other work.

In all figures the absolute configuration has been depicted.

## The Crystal and Molecular Structure of N-Brosylmitomycin A

A. Tulinsky<sup>1a</sup> and J. H. van den Hende

Contribution from the Sterling Chemistry Laboratory, Yale University, New Haven, Connecticut, and Lederle Laboratories, a Division of American Cyanamid Company, Pearl River, New York. Received January 19, 1967

**Abstract:** The structure of N-brosylmitomycin A, a crystalline derivative of an anticancer antibiotic extracted from soil isolates of *Streptomyces verticillatus* strains, has been determined using X-ray crystallographic techniques. The crystals are monoclinic with  $a = 19.70$ ,  $b = 8.24$ ,  $c = 16.05$  Å,  $\beta = 95.80^\circ$ , space group C2, and there are four molecules per unit cell. The structure was solved using the heavy atom method and refined using Fourier and least-squares techniques. The mitomycin molecule contains four fused ring systems, one of which is an aziridine. Evidence was found indicating an interaction between the lone electron pairs of the two ring nitrogen atoms. The molecules are held in the crystal by continuous chains of  $N-H \cdots O$  hydrogen bonds and a strong affinity between bromine atoms and the components of quinoid rings of adjacent molecules. The crystals are solvated with 0.5 mole of benzene/mole of antibiotic located in voids of the structure. The absolute configuration of the molecule has been determined from the comparison of observed and calculated structure factors utilizing the anomalous scattering contribution of bromine and sulfur for Cu K $\alpha$  radiation with respect to alternative atomic positions.

Three soil isolates of *Streptomyces verticillatus*, Lederle strains AA-849, AB-286, and AB-929, were used to produce mixtures of ethyl acetate extractable

from these cultures were compared by paper chromatography they appeared to contain the same groups of antibiotics, five of which were isolated in crystalline form. The characterization of several of these compounds showed that they were identical with mitomycin A, B, and C and porfirimycin, and were of a new and unusual structural type, representing the first naturally occurring examples of an aziridine elaborated by a microorganism.<sup>3a</sup> A considerable amount of chemical degradation and related studies had correctly identified all atoms and their interconnections, but several details which were of interest, such as the relative stereochemistry of the asymmetric carbons, could not be established *via* classical means.

The present paper deals with the structure elucidation using single-crystal, X-ray diffraction methods of the N-brosyl derivative of one of the components of the antibiotic mixture, mitomycin A, of which a preliminary report has appeared elsewhere.<sup>4</sup>

### Experimental Section

Crystals of N-brosylmitomycin A suitable for X-ray examination were obtained by the slow evaporation of a solution of methylene chloride and benzene (1:4).<sup>5</sup> The crystals were deeply colored red laths and occasionally they displayed end-face development. The crystal chosen for X-ray examination also proved to be of sufficient quality for intensity data collection and its dimensions were approximately  $0.8 \times 0.3 \times 0.05$  mm.

The X-ray work was carried out with Cu K $\alpha$  radiation and a General Electric XRD-5 equipped with a single-crystal orienter and a scintillation counter assembly. A preliminary survey of the diffraction pattern indicated that the crystal system was monoclinic with  $a = 19.70$ ,  $b = 8.24$ ,  $c = 16.05$  Å,  $\beta = 95.80^\circ$ . The only reflections that were systematically absent were of the type  $h + k = (2n + 1)$ . Therefore, the space group was either C2, Cm, or C2/m. The latter was eliminated because it is centrosymmetrical and Cm was rejected because it contains a mirror plane (mitomycin A is an optically pure isomer). The space group C2 was verified upon examining the Patterson function of the crystal. The bromine-bromine and the sulfur-sulfur vectors and their cross vectors could be interpreted only in terms of the equivalent positions of space group C2.

A chemical analysis of the crystals (dried at  $78^\circ$  under vacuum) indicated an empirical formula corresponding to  $C_{44}H_{48}N_4O_8SBr$ . This carbon content is high by three with respect to the formula of the antibiotic derivative and suggested 0.5 mole of benzene solvate/mole of N-brosylmitomycin A.<sup>6</sup> The solvation was corroborated by flotation density measurements in aqueous potassium iodide solution ( $d_{\text{obsd}} = 1.55$  g cm $^{-3}$ ;  $d_{\text{calcd}} = 1.554$  g cm $^{-3}$ , based on four N-brosylmitomycin A and two benzene molecules per unit cell).

Before initiating three-dimensional, intensity-data collection, the quality of the crystal was assessed by measuring the mosaic spreads of several reflections at different  $\phi$  and  $\chi$  values. The spreads were found to be single peaked and symmetrical, and varied from  $0.4$  to  $0.7^\circ$  in width as a function of  $\omega$  (background to background). The quadrant of reciprocal space that included the narrowest and most symmetrical spreads was selected for intensity measurements. The intensities were obtained using the stationary crystal-stationary counter technique with balanced Ni-Co filters. Of the 1481 reflections accessible to  $d_{\text{min}} = 1.0$  Å ( $2\theta_{\text{max}} = 100^\circ$ ), 1352 (91.3%) were taken to be observable.

Throughout the data collection, the intensities of three convenient reflections were monitored as a function of X-ray exposure to the crystal. During the first 6 hr of exposure, the monitored reflections

remained essentially constant but during the last 6 hr of data collection, they showed a continuous and slow decrease in intensity (maximum decrease of 6% after 12 hr of exposure). Consequently, the latter half of the intensity data was corrected for this fall off. The intensities were also corrected approximately for absorption (as a function of azimuthal angle  $\phi$ ).<sup>7</sup> The absorption correction was found to be  $2\theta$  dependent, and it was approximated with a weighted mean correction that was more appropriate for the higher order reflections. The maximum:minimum ratio of the correction was 2.4. Finally, Lorentz and polarization factors were applied to the modified intensities converting them into relative structure amplitudes.

### The Structure Determination

The structure was solved using the phase-determining, heavy-atom method.<sup>8</sup> A three-dimensional Patterson function was computed sharpened with  $(z_{\text{Br}}/f_{\text{Br}})^3$ , where  $z_{\text{Br}}$  and  $f_{\text{Br}}$  are, respectively, the atomic number of bromine and the scattering form factor of bromine at rest. The effect of such a sharpening procedure is to enhance the bromine-bromine vectors to point bromine atom interactions with thermal motion. The sulfur atom interactions are also enhanced by this procedure, but not as much, while the light atom interactions are sharpened least of all. The bromine-bromine and sulfur-sulfur interactions were readily recognized in the Harker section at  $v = 0$ . From the  $(x, z)$  coordinates thus obtained, the bromine-sulfur interactions in general positions were identified. The latter also gave the relative  $y$  coordinates of bromine and sulfur.

Before proceeding with a structure factor computation, the positions of the two carbon atoms of the brosyl group that are bonded to the bromine and the sulfur atoms were inferred. The procedure was relatively straightforward and involved only the assumptions: (1) that all four atoms lie on a straight line and (2) the bond distances of C-Br and C-S. The crucial point of the procedure proved to be the correct identification of the Br-S vector belonging to a single molecule. There were two vectors of approximately the correct length; however, one could be eliminated because of its close proximity to a twofold rotation axis, thus giving rise to packing problems.

Structure factors were now computed based on the positions of the bromine, the sulfur, and the two inferred phenyl carbon atoms and an isotropic thermal parameter of  $B = 3.0$  Å $^2$ . The calculated phases were then assigned to the observed structure amplitudes and a three-dimensional electron density ( $\rho_c$ ) was computed. This electron density contained 45 peaks greater than  $1.7$  eÅ $^{-3}$  (carbons included in the structure-factor computation are also included in this count). Of these peaks, 30 were shown to belong to the molecule, seven were eliminated because of close approaches to the brosyl system or the bromine atom, and two others were disregarded because they were situated too close to a twofold rotation axis.<sup>9</sup> The remaining six peaks were all positionally isolated from the main body of peaks and eventually were shown to be spurious. At this

(9) Symmetry-related peaks in the present instance belong to independent molecules unless the molecule itself has twofold rotation symmetry and additionally utilizes the crystallographic twofold rotor. Since the latter was not applicable to the antibiotic, the two peaks near the twofold rotation axis would give rise to unacceptably short van der Waals contacts. At a later stage of the work, these peaks were, in fact, shown to belong to the structure, and the way in which they are will be indicated below.

(5) We thank Dr. J. H. Mowat of Lederle Laboratories for preparing the N-brosyl derivative and for growing the crystals.

(6) This observation was also supported with gas chromatographic measurements. We should like to thank Mr. A. Mistretta of Lederle Laboratories for carrying out these measurements.

the brosyl system was easily identified and it was to a three-membered ring (known to be aziridine) in turn was fused to two fused five-membered (see Figure 1). From ring B, the density was that ambiguous; either ring B was fused to a membered ring bearing short side chains (shown by broken lines in Figure 1) or a long side chain emanated from B. Also, there was a two-atom chain at bridgehead position between rings A and B (X) seemingly longer chain at Y.

At this point, consultation with the Lederle group and in the chemical structure determination of the bicyclics revealed a general agreement between their chemical structure and the one described above. Using additional chemical information and the location of smaller peaks ( $1.3\text{--}1.6\text{ eA}^{-3}$ , marked by asterisks in Figure 1) the remainder of the structure shown in Figure 1 (as broken lines) was recognized. Two of the smaller peaks proved to be part of a quinone system bearing methyl and methoxyl groups. The other smaller peak formed part of a carbamoyloxymethyl chain ( $\text{CH}_2\text{OCONH}_2$ ) (side chain Y, partially shown). Finally, the fused five-membered rings were finally known to be a pyrrolizine system (contained bridgehead nitrogen).

Structure factor and electron-density computations were now carried out: (1) the first ( $\rho_1$ ) based on complete structure including atoms of correct chemical identity, and (2) the second ( $\rho_2$ ) included bromine, sulfur, and 25 carbon atoms (the crystallographically ambiguous structure; solid line structure of Figure 1). Both computations included an over-all isotropic temperature factor of  $B = 3.0\text{ \AA}^2$ . The latter computation was performed as a precautionary measure and also to compare the results of including the complete structure. Temperature factors for these structure factor computations were 0.22 and 0.28, respectively.

Comparison of the two resulting electron densities showed that 32 of the atoms included in the computation of  $\rho_1$  included atoms (except two in  $\rho_2$ ) in both densities increased 2.5 times or more. The two atoms which remained stationary in  $\rho_2$  (the methyl of the bridgehead ethyl and the carbamate nitrogen) had other real peaks ( $\sim 1.6\text{ eA}^{-3}$ ) within bonding distance of groups. In the end, it was shown that an incorrect choice was originally made in both instances.

Atoms not included in structure factor computations remained essentially unchanged or increased in height in  $\rho_2$ . Nitrogen and oxygen atoms, in contrast to carbon, appeared  $1\text{--}3\text{ eA}^{-3}$  greater than the carbon atoms in this density and confirmed the chemical identities employed to obtain  $\rho_2$ . Finally, all small peaks of  $\rho_1$  decreased or became vanishingly small in both  $\rho_2$  and  $\rho_3$ .

Two peaks ignored in  $\rho_1$  because they were too close to a twofold rotation axis ( $\approx 1.2\text{ \AA}$ ) persisted and increased in height in both  $\rho_2$  and  $\rho_3$ . Furthermore, two peaks developed significantly in this region ( $0.5\text{ eA}^{-3}$ ) and they were located on the twofold axis. It became apparent that these peaks represented the molecules which were utilizing twofold rotational symmetry to accommodate along the crystallographic twofold rotor. Thus, the 0.5 mole of benzene of solvation was satisfactorily accounted for since the multi-

Figure 1. Atomic arrangement identifiable from  $\rho_1$  and inferred from chemical considerations.

licity of the twofold position in space group C2 is two.<sup>10</sup>

Refinement of the structure, including a half-benzene molecule, was now commenced through electron- and difference-density computations. After one cycle, individual isotropic thermal parameters were obtained from the difference density and these were included into structure factor computations. In all, six cycles of refinement were carried out in this manner and  $R$  decreased to 0.146. At this stage, refinement by the method of least squares was initiated.

### The Least-Squares Refinement

The structure was first refined by conventional diagonal least-squares techniques. The weighting scheme adopted assigned unit weights ( $w = 1.0$ ) to all reflections with  $4|F_{\min}| < |F| < 10|F_{\min}|$ ;  $w = |F|/4|F_{\min}|$  when  $|F| \leq 4|F_{\min}|$ ; and  $w = 10|F_{\min}|/|F|$  for reflections with  $|F| \geq 10|F_{\min}|$ . This scheme resembles the Hughes weighting and simultaneously takes into account variations in the measured intensity data due to the counting statistics. Isotropic refinement converged after three cycles in which only the non-zero structure amplitudes were included and an  $R$  of 0.109 was obtained. A three-dimensional electron density map was calculated at this stage and it clearly indicated a large amount of anisotropy for both the bromine and sulfur atoms. This was allowed for in some additional refinement by introducing both heavy atoms as slightly separated, but thermally coupled half-atoms. A considerable improvement in bond distances and valency angles resulted but  $R$  was not affected much.

Inclusion of all atoms with anisotropic correction factors and subjecting the data to additional refinement yielded a large change in  $R$ , which became stationary at 0.087, and caused significant changes in some of the bond distances. A difference density map was computed, but in general the regions in which the hydrogen atoms were expected to be located were poorly defined. Therefore, the refinement process was terminated. The final positional and anisotropic thermal parameters are given in Table I, and the standard errors of the positional parameters are given in Table II. (The observed and calculated structure factors are available from the authors.)

(10) It should be remarked here that from the onset of the work, the one half mole of benzene of solvation was puzzling, especially in view of the fact that the crystal proved to be an excellent X-ray scatterer (91.3% of the data was observable to 1- $\text{\AA}$  resolution). Such behavior was not consistent with disordered benzene of solvation as the one half mole would suggest.

<sup>a</sup> The anisotropic temperature factors which were used in the calculations were of the form  $T = e^{-(B_{11}h^2 + B_{22}k^2 + B_{33}l^2 + 2B_{12}hk + 2B_{13}hl + 2B_{23}kl)}$ . All *B* values are multiplied by a factor of 10<sup>4</sup>.

## Structure of the Molecule

An inspection of the interatomic distances (Figure 2) shows that there are few anomalies present in the structure of N-brosylmitomycin A. Major interest

Figure 2. Final bond distances.

lies with the aziridine ring system, which consists of three bonds of equal length. The C-N distances of 1.48 and 1.49 Å are normal for single carbon-to-nitrogen bonds. The exocyclic bond angles N(1)-C(1)-C(3) of 110.7° and N(1)-C(2)-C(4) of 112.8° (Figure 3;

see Figure 4 for labeling) indicate that the carbon atoms tend to retain their tetrahedral configuration despite the considerable shortening of the C-C bond to 1.48 Å. The atoms C(4), C(2), C(1), and C(3) of ring A are coplanar. The angle between the plane defined thusly and the aziridine ring is 104°, and the distance between the indole nitrogen N(2) and N(1) is 2.69 Å.

As one would expect, N(2) behaves much like an amide nitrogen owing to its ability to participate in the conjugation of the quinoid system. However, it is observed in ultraviolet absorption spectra that mitomycin A is bathochromic with respect to model compounds<sup>3b</sup> and that its extinction coefficient is considerably smaller, which is indicative of a lower energy system.

This may be accounted for by the fact that N(2) is observed to be nonplanar and thus is impaired in its ability to take part in the conjugation. N(2) is 0.3 Å out of the plane defined by C(3), C(4), and C(7), and on the opposite side of that plane as the aziridine nitrogen, N(1). Furthermore, an inspection of the bond angles shows that it is more tetrahedral than trigonal. Even though one could ascribe this to the fact that

Figure 3. Final bond angles.

is part of two five-membered rings and therefore subject to distortion of its valency angles, a more plausible reason becomes obvious upon inspecting the orientation and position of the orbitals occupied by the free electrons of N(1) and N(2). If N(2) were planar these would be subject to overlap, and the ob-

Figure 5. Schematic view of interaction of unshared electrons.

served deformation of N(2) is sufficient to avoid this to a great extent, as is indicated in Figure 5.

The nonplanarity of N(2) also affects other parts of the molecule. The substitution of an amide-type nitrogen at C(7) and an O-Me group at C(9) would, in the case of a normal planar molecule, be expected to result in: (a) a shortening of the C-N single bond owing to its participation in the conjugated system, (b) a simultaneous lengthening of the double bond C(7)-C(6), and, possibly, (c) a shortening of the C-O-Me bond due to the influence of the *p*-mide group.

It is observed that the C-N bond is indeed shortened. However, no shortening of the C-O bond is observed,

Figure 6. Projection of crystal structure as viewed along the *c* axis (one-half unit cell shown).

Figure 7. Hydrogen-bonding scheme.

which may be attributed to the fact that N(2) is not coplanar with the quinoid system, so that hyperconjugation with O(7) is not expected to occur.

From the above it may also be concluded that the nonbasic behavior of N(1) which is atypical for an aziridine nitrogen atom, even when part of a [3.1.0] bicyclo system, is due to the steric interference of its fourth valence pair with the free *p* orbital of N(2). In the free base this should also inhibit its ability to invert, as is indicated in nuclear quadrupole measurements. N(1) may therefore actually be considered as an optically active site produced by steric interference.

Some interesting observations may also be made about the brosyl group. First, the sulfonyl group is nearly tetrahedral with the exception of the angle between the O-S-O bond, which is 123°. Second, the bromine atom is nearly equidistant to the carbon atoms

forming the quinoid ring of another molecule (see Table III). From the foregoing, it is reasonable to conclude that there is a negative charge present on the oxygen atoms of the sulfonyl group causing the increased O-S-O angle (SO<sub>2</sub> is a more electron-withdrawing group than bromine). The bromine atom in turn compensates for this by interacting with the quinoid system.

The observed N-S distance of 1.663 Å shows that this bond contains some double bond character. No comparison is possible with similar systems since the literature contains only one reference to a N-S bond, that in SO<sub>2</sub>(N(CH<sub>3</sub>)<sub>2</sub>)<sub>2</sub>, where it is found to be 1.623 Å.<sup>11</sup> A single bond would probably have a length of about 1.73 Å [derived from atomic radii of S (1.04 Å), N (0.74 Å), and an electronegativity correction for N-S of -0.05 Å].

Figure 8. Arrangement of the molecules as viewed along the *b* axis.

### Molecular Packing in the Crystal Lattice

The structure is held together *via* infinite chains of hydrogen bonds in the direction of the *b* axis between the side functional groups of different molecules, as may be seen from Figures 6 and 7. The N-H...O distance of 2.817 Å indicates a fairly strong interaction. This hydrogen-bonding scheme provides within each unit cell parts of two sets of these chains which seem to be joined together by the donor-acceptor relationship of the bromine and quinoid groups already discussed. It is within this framework that the benzene molecules of solvation are located in such a way as to provide the greatest number of possible van der Waals contacts. A complete listing of all intermolecular distances smaller than 4 Å is given in Table III. Figure 8 provides a schematic view of the molecular packing as viewed in the direction of the *b* axis and clearly delineates the solvate-containing channels.

### Absolute Configuration Determination

At the time when the absolute configuration of the molecule became of interest, the crystal used for data

Figure 9. Absolute configuration.

collection was no longer available for intensity measurement of the reflections for which the largest deviations from Friedel's law could be expected. However, it is possible to determine the hand of the molecule without knowledge of these data by computing *R* values for selected sets of reflections with large differences between the calculated structure amplitudes for the two enantiomorphs.<sup>13</sup>

For the 67 reflections with differences of more than 10%  $|F_o|$ , and magnitudes larger than 15 (electron-scattering units), it was found that when the reflections were assigned as (*hkl*), *R* was calculated as 0.150; however, if they were considered to be of the type ( $\bar{h}\bar{k}l$ ), *R* was 0.122. This procedure was repeated for all reflections with  $|F_o|$  larger than 25, in which case the results were 0.153 and 0.109, respectively. This clearly suggests that the hand which was originally chosen was incorrect,<sup>13</sup> and the absolute configuration of mitomycin A determined in this manner is depicted in Figure 9. In addition to the two *R* values for the large differences it was found that the over-all *R* values (0.094 and 0.087) were also consistent with the above.

# Reactions of Carbon Vapor. IV. Reactions of Metastable Carbon Atoms ( $^1S$ ) with Olefins<sup>1,2</sup>

P. S. Skell and R. R. Engel<sup>3</sup>

Contribution from the Department of Chemistry, The Pennsylvania State University, University Park, Pennsylvania 16802.

Received January 20, 1967

**Abstract:** Carbon atoms have been produced in a low-intensity carbon arc under high vacuum, a method which yields a mixture of ground-state ( $^3P$ ) and metastable excited-state species ( $^1D$  and  $^1S$ ). Using a 16-v (ac) arc, the metastables are the most abundant. The chemistry of the  $^1S$  species in reactions with olefins is reported here; it reacts with one molecule of olefin by insertion into the double bond to form an allene.

We have previously reported the reactions of olefins with ground-state ( $^3P$ ) carbon atoms produced in a low intensity carbon arc under high vacuum.<sup>4-6</sup> We now report on the reactions of these olefinic substrates with carbon atoms in the metastable excited  $^1S$  state.

The  $^1S$  state of atomic carbon is known to lie 2.7 eV above the ground state.<sup>7</sup> Yilmaz has predicted the radiative half-life of  $^1S$  carbon atoms on purely theoretical bases<sup>8</sup> to be 2 sec for the process  $^1S_0 \rightarrow ^1D_2$ .

Calculations using the Boltzmann equation

$$(n_{1S}/n_{3P}) \propto e^{-2.7\text{eV}/kT}$$

would indicate that at an arc temperature of 5000°K much less than 1% of the vaporized atomic carbon would be in the  $^1S$  state. However, Ornstein, *et al.*,<sup>9</sup> and later Mason<sup>10</sup> found that the distribution among excited states of species Ba<sup>9</sup>, Zn<sup>9</sup>, CN<sup>10</sup> in a low-pressure arc is not described by the Boltzmann relation. Electronic excitations greatly in excess of that predicted from the Boltzmann equation were observed. The explanation given was that excitation was caused by electron bombardment in the absence of an equilibrating medium, *e.g.*, air. This mechanism of excitation has been demonstrated to apply in arc and hot-filament vaporizations of carbon species (unpublished results).

In our system where the pressure in the region of the arc is  $\sim 10^{-4}$  torr (mean free path of  $\sim 50$  cm), one might expect significant quantities of atomic carbon in the  $^1S$  state to be produced.

The reactions of  $^{12}\text{C}$ , produced by nuclear transformation processes, with ethylene have been extensively studied.<sup>11-14</sup> In this system allene has been

found to be an important product (18%). However, owing to difficulties previously discussed,<sup>6</sup> it is not possible to define which electronic state of carbon is producing the allene.

By analogy with other carbene reagents, a carbon atom would be expected to add to the double bond of an olefinic substrate producing a cyclopropylidene intermediate.

A major reaction pathway for cyclopropylidenes prepared in solution is rearrangement to allenic products.<sup>15-18</sup>

However, since these species were generated in the presence of strong Lewis bases in the reaction media, they were probably complexed by these bases and were not "free carbenes." In the system used for our work the species would be expected to be "free" as there is only hydrocarbon present.

This paper describes the reactions of  $^1S$  carbon atoms with olefins; the only products in significant amounts are the allenes resulting from insertion of the carbon atom into the double bond.

## Method

The carbon arc and molecular flow system used in this study were as previously described.<sup>19</sup> In all of these

ions a 16-v (ac) arc was employed which produced mixture of ground- and excited-state carbon atoms all as triatomic carbon. The arc current shows fluctuations in intensity going as high as 100 amp averaging about 40 amp. Time-delay reactions were as previously described using a neopentane matrix.<sup>6</sup>

The allenic products were separated from the excess rate by fractional distillation using a  $36 \times 0.5$  in. jacketed column packed with glass helices, followed by vacuum distillation and gas phase chromatography. They were identified by their infrared mass spectra, measured on the materials collected from the gas chromatograph. A 22-ft column (0.25 in. diameter) of 30% hexamethylphosphorotriamide on Chromasorb P was used.

## Results and Discussion

**Electronic State of Carbon Atoms Leading to Allene. Time-Delay Studies.** In carbon vapor reactions of olefins using continuous arcing with continuous deposition of substrate, the allene, resulting from reaction of the carbon atom into the double bond, was produced to the extent of  $\sim 45\%$  of the carbon atom reaction product (*vide infra*), the remainder being distributed among a number of products.

By depositing a layer of neopentane ( $\sim 2$  g) on the liquid nitrogen cooled walls of the reaction flask and operating the carbon arc for a short period of time ( $\sim 0.3$  sec)  $\sim 0.3$  mg of vaporized carbon can be deposited. This amount of carbon, diffusion into the matrix continuously occurs. If  $\sim 5$  g of reactive olefin is added later, causing temporary liquefaction of the system, all products found in the "continuous" reaction are present, except for the allenic product which has essentially disappeared. The carbon atom precursors for allenes have decayed to a lower electronic state in this process.

By noting the amount of allene present after a time delay,  $\sim 2\%$ , the half-life of this precursor has been estimated at  $\sim 2$  sec.<sup>3</sup>

It is reasonable to assign to the allene-forming carbon atoms the designation of  $^1S$  on the following bases: the decay of this species of excited carbon increases the amounts of products resulting from both ground-state ( $^3P$ ) and another excited-state ( $^1D$ ) carbon species; this species brings higher energy to the transition (as is shown by the products, allenes *vs.* cyclopropane ring formation) than the  $^3P$  and  $^1D$  state species (*infra*).

**Reaction of  $^1S$  Carbon Atoms with Isobutylene.** The reaction of  $C_1(^1S)$  with isobutylene formed, as the product which can not be attributed to  $^3P$  and 3-methyl-1,2-butadiene which was identified by comparison of its infrared and mass spectra with those of the known material. The 3-methyl-1,2-butadiene comprised up to 40 mole % of the atomic carbon reaction products.

using a 16-v (ac) carbon arc.

**Reaction of  $^1S$  Carbon Atoms with 1-Butene.** Reactions with 1-butene yielded a single product, 2,3-pentadiene, which could be attributed to the  $C_1(^1S)$ .

It was identified by comparison of its infrared mass spectra with those of the known compound.

In the reaction using a 16-v (ac) carbon arc, the 1,2-pentadiene made up 45 mole % of the total carbon atom reaction product.

**D. Reaction of  $^1S$  Carbon Atoms with Propylene.** The sole product attributable to the reaction of  $^1S$  carbon atoms with propylene was the 1,2-butadiene which accounted for 45 mole % of the total product from carbon atom reactions using a 16-v (ac) arc. It was identified by comparison of its infrared and mass spectra with those of the known compound.

**E. Reaction of  $^1S$  Carbon Atoms with *cis*- and *trans*-2-Butene.** From the reaction of either *cis*- or *trans*-2-butene with  $^1S$  state carbon atoms, 2,3-pentadiene is the only product, from *cis*-2-butene 42 mole % and from

*trans*-2-butene 43 mole % of the total carbon atom products.

The 2,3-pentadiene was identified by comparison of its infrared and mass spectra with those of the known material.

The earlier report<sup>4</sup> of this reaction indicated two products from  $^1S$  carbon atoms, 2,3-pentadiene and an unidentified substance. The latter, on separation from the other components of this distillation fraction, proved to be 2,3-pentadiene; it had been trapped with the higher boiling reaction products, and its identity was not recognized immediately because different gas chromatography columns were used for further analysis of the low- and high-boiling fractions.

**F. Reaction of  $^1S$  Carbon Atoms with 1,3-Butadiene.** The reaction of 1,3-butadiene with  $^1S$  carbon atoms yielded a product not found in  $^3P$  and  $^1D$  reactions, a single substance easily separated from the excess substrate and assigned the structure of 1,2,4-pentatriene on the basis of its infrared and mass spectra. Its infrared spectrum corresponded to that reported for 1,2,4-pentatriene<sup>20</sup> and its low-voltage mass spectrum showed

a parent peak at  $m/e$  66 corresponding to  $C_5H_6$ . Using a 16-v (ac) arc 1,2,4-pentatriene comprises 47 mole % of the total carbon atom reaction products.

**G. Competition Reactions of Olefins for  $^1S$  Carbon Atoms.** Competition reactions were run by equilibrating a known mixture of the olefins in the vacuum line and depositing this mixture on the cooled walls of the reaction flask while arcing. The reaction mixture was handled in the usual manner; product analysis was done by gas chromatography. The relative rates can then be calculated from the relative amounts of products. The results are shown in Table I. Although the differences are small, the order of reactivities

Figure 1. Energy profile for reaction of atomic carbon with olefins.

is in accord<sup>21</sup> with the proposal of a singlet attacking species of low selectivity.<sup>22,23</sup>

Table I

Olefin	Rel rate of reaction with C <sub>1</sub> ( <sup>1</sup> S)	Product
	1.44	
	1.06	
	1.92	
	5.21	
	(1.00)	

**H. Reaction of <sup>1</sup>S Carbon Atoms with a Mixture of 1-Pentene and *cis*-2-Pentene.** The reaction of <sup>1</sup>S carbon atoms with a mixture of 1-pentene and *cis*-2-pentene (ratio of 1.35:1.0) yielded two products, 1,2-hexadiene and 2,3-hexadiene, in the ratio 3.1:1.0. They were identified by comparison of their infrared and mass spectra with those of the known compounds.

These two products accounted for 25% of the total carbon vaporized using a 16-v (ac) arc (38% of the atomic carbon).

(21) The high relative reactivity of 1-butene is anomalous. Although in the other cases (sections H and I) the  $\alpha$ -olefinic site is attacked more readily than the internal site, the differences are not as great as here. We have no explanation for this unusual reactivity.

(22) P. S. Skell and A. Y. Garner, *J. Am. Chem. Soc.*, **78**, 5430 (1956).

(23) W. von E. Doering and W. A. Henderson, Jr., *ibid.*, **80**, 5274 (1958).

This result indicates that the <sup>1</sup>S carbon atom reacts 2.3 times as rapidly with the  $\alpha$ -olefinic site as with the internal olefinic site.

**I. Reaction of <sup>1</sup>S Carbon Atoms with 1,5-Heptadiene.** From the reaction of <sup>1</sup>S atomic carbon with 1,5-heptadiene (one peak on gas chromatograph; presumably one isomer), two products were obtained, 1,2,6-octatriene and 1,5,6-octatriene, which were identified by their infrared and mass spectra.

These two products were formed in the ratio 2.7:1.0, insertion into the  $\alpha$ -olefinic site being favored over insertion at the internal olefinic site. This result compares favorably with that for a mixture of 1-pentene and *cis*-2-pentene (*vide supra*).

Using a 16-v (ac) arc, these two products accounted for 28% of the total carbon vaporized (42% of the atomic carbon).

**J. Conclusions.** In the time-delay experiments, carbon deposited on a neopentane matrix, using a delay of 15 sec, the only substances not present in the product mixtures being the allenes. After 15 sec most of the <sup>1</sup>D atoms are still present; they do not react with olefins to form allenes. Moreover, the decay of the precursor of the allenes enhances the yields of all of the <sup>1</sup>D products<sup>24</sup> by approximately the same factor, i.e., their total yields are increased but they remain in about the same proportion, except for the spiropentanes (also derived from <sup>3</sup>P).

Thus, the <sup>1</sup>S carbon atoms are the only species leading to the formation of allenes. Also, it seems as if the allenes account for all or almost all of the <sup>1</sup>S carbon produced. Small amounts of the <sup>1</sup>D products may be formed from <sup>1</sup>S carbon atoms but certainly not large quantities, unless they are coincidentally produced in the same proportions as from the <sup>1</sup>D atoms. If such were the case, it would necessitate a common intermediate for the reactions of <sup>1</sup>S and <sup>1</sup>D carbon atoms which is not in accord with the evidence (*vide infra*).

It has been established that the reaction of <sup>1</sup>D carbon atoms with olefinic substrate leads to the formation of a singlet cyclopropylidene intermediate.<sup>25</sup> This intermediate then reacts with a second molecule of olefin leading to products. None of this intermediate rearranges to allene under our reaction conditions: liquid nitrogen cooling and a high concentration of olefin.

(24) Reports on the details of the reactions of the <sup>1</sup>D state will be presented elsewhere.

(25) Reference 2 and unpublished results.

the energy of activation for rearrangement must be lower than the energy of activation for addition to the other molecule of olefin (Figure 1). At room temperature in solution rearrangement of singlet cyclopropylenes to allenes takes place readily,<sup>15-18</sup> in competition with olefin addition.

The <sup>1</sup>S atom addition to an olefin should have a resemblance to the <sup>1</sup>D addition, the major difference being the 33-kcal/mole extra energy brought to the transition state by the higher energy atom. If this hot singlet cyclopropylidene were an intermediate of life-time sufficient to permit trapping by olefins, the yields of allenes would vary with changing the substituents and R' since these substituents would be expected to

influence the rate of ring opening to the allene. This is the case, the yields of allenes being 40-47% with variation in substituents reported here. Thus it follows the hot singlet cyclopropylidene is not a trap-

pable intermediate. For <sup>1</sup>S + olefin the cyclopropylidene configuration may only represent a transition state.

Since the activation energy for ring opening of a normal singlet cyclopropylidene (from <sup>1</sup>D) is small, the species in the reactions of C<sub>1</sub>(<sup>1</sup>S) may bypass this configuration and go directly to the allene; the hot species may not be able to lose its surplus energy fast enough to lead to a thermally equilibrated cyclopropylidene intermediate.

The relative reactivities of olefins in competition for <sup>1</sup>S atoms is not highly informative since the spread of reactivities is small. Perhaps it is most significant that butadiene is less reactive than monoolefins, ruling out transition states with radical character.

An interesting and disturbing feature of these matrix systems must relate to their physical nature. The striking differences in reactivity of CH<sub>3</sub> groups for <sup>1</sup>S insertions in neopentane and isobutane was noted earlier in this study. Perhaps for related reasons the double bond of 1-butene is more reactive than those in propene, 1-pentene, and 1,5-heptadiene (terminal bond). No electronic rationalization of this effect is apparent.

## A Simple Theory for Predicting the Effects of Substituent Changes on Transition-State Geometry<sup>1,2</sup>

Edward R. Thornton

*Contribution from the Department of Chemistry, University of Pennsylvania, Philadelphia, Pennsylvania. Received December 5, 1966*

**Abstract:** A simple technique for analyzing the effects of substituent changes on transition-state geometry is outlined. The basic idea is to consider the effects of substituents as linear perturbations of the vibrational potentials for the normal coordinate motions both parallel to and perpendicular to the reaction coordinate motion. Effects parallel to the reaction coordinate then correspond closely to predictions based on "Hammond's postulate," while effects perpendicular to the reaction coordinate introduce a previously neglected effect which is expected to be smaller than the parallel effect in many, but not all, cases. Examples of application of the theory to S<sub>N</sub>2, E2, S<sub>N</sub>1, and other reaction mechanisms are presented. The theory is discussed in terms of the forces on nuclei predicted by the Hellmann-Feynman theorem. Using precise potential energy curves for diatomic molecules calculated by computer from spectroscopic data, it is concluded that the approximation that the perturbation is linear, if a relatively small substituent change is made, is probably a very good one. The result is: (1) any substituent change which makes an increase (decrease) in the normal coordinate *X* of a molecule or transition state more difficult will lead to a perturbed equilibrium geometry in which *X* is decreased (increased) if the force constant for *X* motion is positive, but in which *X* is increased (decreased) if the force constant for *X* motion is negative; (2) the effect of a substituent change on a normal coordinate motion can be predicted from the effect of the substituent on the reacting bond(s) nearest to the substituent and involved in that motion; (3) when two reacting bonds are equidistant from the substituent, the effect of the substituent should be nearly equal on both if both are of the same strength in the unperturbed transition state, but should be greater on the stronger than on the weaker (and greater on a σ than on a π bond); (4) an electron-supplying (withdrawing) substituent should make a bond more difficult to extend (compress) if attached to the basic, i.e., more electronegative atom, end of the bond, but more difficult to compress (extend) if attached to the acidic, i.e., less electronegative atom, end of the bond; (5) the substituent effect on geometry is the sum of individual effects on each normal coordinate.

Since substituent effects upon a stable molecule's structure, energy, and other properties are reasonably well understood in a qualitative way, it is fascinating to try to apply this qualitative understanding to

predict the effects of the substituents on the structure, energy, and other properties of transition states, or

Figure 1. (a) Contour surface for the reaction  $A + BC \rightarrow AB + C$ . Contours of constant (electronic) potential energy for nuclear displacement plotted as a function of the bond distances  $r_{AB}$  and  $r_{BC}$ . The reaction coordinate is the dashed line. Parallel and perpendicular motions are shown as double-headed arrows. The reaction is assumed to proceed without any bending of the ABC angle from  $180^\circ$ , so that the potential energy depends only on  $r_{AB}$  and  $r_{BC}$ . (b) Plot of potential energy vs. distance along the reaction coordinate.

activated complexes, for various reactions. The relative success of transition-state theory<sup>3</sup> in describing and making predictions about rates and mechanisms of thermal reactions, together with the considerable (though approximate) theoretical justification of the method, make it reasonable to discuss reaction mechanisms in terms of a transition state of definite geometry corresponding to the point of highest electronic energy<sup>4</sup> along the most favorable path by which reacting molecules may be converted into products. Other, necessarily higher energy, reaction paths exist which do not pass through the transition-state geometry.

The motion corresponding to the reaction coordinate which has negative restoring force at the transition

state is shown as a dashed line in Figure 1 for the simple case of a linear approach of A to BC, A displacing C.

Since a transition state is defined as being at a potential energy extremum (saddle point) and, therefore, its internal nuclear motions consist of vibrations analogous to the normal vibrations of stable molecules in the sense that, at the geometry of the extremum, no forces act on the nuclei, it is not unreasonable to suppose that structural predictions based on principles established for stable molecules would carry over in considerable detail to transition states. The "Hammond postulate"<sup>5</sup> and various extensions<sup>6</sup> have been used to make predictions about transition-state geometry from reactant, intermediate, and/or product geometries and enthalpies of reaction. A noteworthy, early example of the application of principles similar to those of the Hammond postulate is the explanation of the Brønsted catalysis law<sup>7</sup> in terms of the crossing of potential energy curves for the bonds being made and broken in a proton-transfer reaction, e.g.

Although these generalizations seem fundamentally reliable, certain experimental results seem to conflict<sup>8</sup> with predictions, and a "rule" has been suggested<sup>9</sup> which seemed to correlate all known data. In analyzing the results of our<sup>2a</sup> and other studies of E2 (elimination, bimolecular) reactions, certain ambiguities and inconsistencies were discovered. A major ambiguity is that the statement of this rule<sup>9</sup> in terms of "reacting bonds" and "reacting orbitals" implicitly assumed that there was only one reacting bond in a single reacting orbital, whereas E2 transition states clearly involve more than one. It might be possible to modify the rule to eliminate the ambiguity. However, the present author believes there are inconsistencies in the (admittedly *a posteriori*) theoretical model, the major one being the assumption that because supplying electrons to, say, the X group of a X-Y bond is expected to make that bond longer at the transition state (of a reaction in which that bond is being made or broken), the increased X-Y bond length implies a decreased electron supply at Y. It now seems almost certain that supply of electrons to X would, while increasing the X-Y bond length, nevertheless increase the electron supply at Y;<sup>9</sup> the predictions of the rule would then be reversed in certain cases.

Although approximate models tend to justify it, an assumption equivalent to the idea that "if a bond is

(8) C. G. Swain and E. R. Thornton, *J. Am. Chem. Soc.*, 84, 817 (1962).

(9) This conclusion can be approximately justified by considering that the primary effect will be electron supply to X and therefore to Y. The primary effect will be partly offset by the secondary effect of increased X-Y bond length, but only partly offset because in the Born-Oppenheimer approximation electron motions determine the motions (and, therefore, the average positions) of the nuclei, not the other way around.

harder to break, it will become more broken at the transition state" is usually required for such predictions. The type of assumption is very hard to justify in its full form because of the property of a transition state that its energy is the *minimal energy maximum*, i.e., the maximum barrier required by the most favorable reaction path. Expressing the properties of functions that have simultaneous minima in one or more dimensions and maxima in another is difficult to do in any way which leads to generalizations.

The problems which arose in application of the above generalizations made it seem likely that a new approach was required. The basic innovation of the "rule" was the derivation of transition-state structural effects directly, rather than by comparison with reactants, products, or intermediates, all of which differ in energy by relatively large amounts from the transition state.<sup>10</sup> The prediction of the effect of substituents on transition-state structure, if possible, was clearly desirable. It then became obvious that previous generalizations had largely considered such effects in terms of geometric changes "along the reaction coordinate," i.e., changes in fraction of product-like character of the transition state, and had all but ignored effects upon all modes of vibration of the transition state, i.e.,

of the transition-state geometry perpendicular to the reaction coordinate. These "parallel" and "perpendicular" directions are shown as arrows in Figure 1, corresponding to the tangent to the reaction coordinate at the transition-state point and the perpendicular to the tangent. In the simple case illustrated in Figure 1, where there are only two geometric variables—two bond lengths—it can be seen that the parallel motion stretches one bond while compressing the other, while the perpendicular motion either stretches or compresses both bonds simultaneously.

A simple perturbation method has emerged which (at least in principle) takes account of both parallel and perpendicular shifts in transition-state geometry. It is outlined, illustrated, criticized, and approximately justified in the following sections.

**Simple Perturbation Method.** In analyzing the effect of a substituent on a transition state, we are interested in determining the effect on each bond in turn. This will be quite straightforward for a stable molecule in which one had adequate empirical and theoretical data to predict how a substituent (say, electron supply) should change the force constant or bond strength (of which type of bond). For a transition state there is a complication that motion of the nuclei along the reaction coordinate is not a truly vibrational motion (it has a negative restoring force), though motion corresponding to all the other normal vibrations of the transition state is truly vibrational (with positive restoring force). Substituent effects upon motions with positive and negative restoring forces turn out to have opposite geometric effects; therefore, one must consider which nuclei actually move in the reaction coordinate motion.

The nuclei of the transition state may in principle

Figure 2. Plots of parabolic potentials,  $V$ , together with the perturbations,  $P$ , which, when added to  $V$ , give the new parabolic potentials,  $V'$ . Note that the slope of  $P_a$  is exactly equal to the slope of  $P_b$ . (a) Effect expected for perpendicular motion; (b) effect for parallel motion.

move during the reaction coordinate motion (though some may be prohibited from moving by symmetry), but the major displacements will undoubtedly be of those nuclei which participate in bonds that are being made or broken during the course of reaction. Such *reacting bonds*<sup>a</sup> can be singled out for study. It can be assumed that groups attached through nonreacting bonds to the nuclei involved in the reacting bonds will approximately follow along with those nuclei as the reacting bonds undergo reaction-coordinate motion. Furthermore, if the reaction coordinate motion involves largely changes in length of reacting bonds (as would be the case in many reactions), bending motions may reasonably be left out of consideration. The case where only one reacting bond is present (relatively unusual) is simplest. In this case the only important motion corresponding to the reaction coordinate is the stretching (for a dissociation reaction) or compression (for an association reaction) of the reacting bond. A plot of energy vs. bond length will then look like the curve in Figure 1b, but the abscissa will not be the curved reaction coordinate shown for the displacement reaction of Figure 1a; the abscissa will simply be the length of the reacting bond.

The vibrational energy of a molecule is a nearly quadratic function of the displacement of the nuclei from their equilibrium positions. The effect of a substituent upon one of the bonds of a molecule is to make small changes in energy, equilibrium bond length, and force constant. Since such effects are relatively small, it can be expected that they will be approximately described by the addition of a linear function of distance to the reference, "unperturbed" curve.<sup>12</sup> The result for a model with a parabolic potential energy function and an exactly linear perturbation is shown in Figure 2a. The shift in the energy of the extremum is caused mainly by the vertical position of the linear perturbation, but the extremum also shifts to longer or

<sup>10</sup> The danger of "crossover" effects (or even "double-cross" effects) potential energy curves for differently substituted systems is considerable in some cases.<sup>11</sup>

J. D. Roberts, "Notes on Molecular Orbital Calculations," Benjamin, Inc., New York, N. Y., 1962, p 93; R. D. Brown, *Rev. (London)*, 6, 72 (1952).

<sup>12</sup> This approach was originally suggested by a discussion of secondary isotope effects in terms of such perturbations, given by E. A. Halevi, *Progr. Phys. Org. Chem.*, 1, 109 (1963). A similar technique has also been used for discussion of the changes in geometry and energy of ordinary molecules upon addition or removal of an electron to form ions and upon electronic excitation: J. P. Malrieu, *Theoret. Chim. Acta*, 4, 434 (1966).

shorter bond length. The same perturbation in fact causes a greater shift of bond length the less the curvature of the unperturbed curve, as will be shown below. The effect of substituents on bond geometry can, therefore, be predicted (approximately, of course) as in Figure 2a by empirically or theoretically estimating the slope (sign and magnitude) of the perturbation. Although it is assumed that the perturbation is linear, the *direction* of the effect is dependent mainly on the slope (positive or negative) of the perturbation at the point of the unperturbed extremum.

In the case of Figure 2a, if we assume that the perturbation slope was caused by adding an electron-supplying substituent to the molecule, it can be interpreted as follows: the electron-supplying substituent makes bond extension more difficult and bond compression easier. Such an effect probably explains the effects of substituents on the O-H stretching vibrations of substituted phenols;<sup>13</sup> electron-supplying substituents in the phenyl ring increase the vibration frequency.

In the case of a transition state, the potential energy as a function of distance along the reaction coordinate (Figure 1b) can be approximated as an inverted parabola in the region of the potential energy maximum, as shown in Figure 2b. There is no theoretical reason why the effects of substituents in perturbing the potential energy along the reaction coordinate should be different from substituent effects on true molecular vibrations. The same linear perturbation shown in Figure 2a produces the dashed curve of Figure 2b, and it can be assumed with considerable confidence that the resulting change in geometry would be observed for a substituent change which made motion (from left to right) along the reaction coordinate *more difficult*.

Empirical data, which will aid in making predictions about ionic reactions where charge accumulation or dispersal occurs, are available; prediction is more difficult for radical or molecular reactions. Hopefully, further data on stable molecules, such as effects of substituents on vibrational frequencies, will give predictions of the direction of the perturbation for most kinds of bonds.

The basic ideas described can readily be applied to reactions having more than one reacting bond. Several reacting bonds can be considered simultaneously by considering the normal vibrations of the transition state and estimating the effects of substituents on the normal vibrations,<sup>14</sup> e.g., the parallel and perpendicular motions in Figure 1a. Each normal vibration can be considered to have a potential energy curve as a function of normal coordinate displacement similar to Figure 2a, except the reaction coordinate motion, which will be similar to Figure 2b.

In many cases only the reacting bonds closest to the substituent will be important in determining the perturbation, provided one can estimate their relative displacements in the normal coordinate motions. It is essential to consider at least two reacting bonds simultaneously if they are equidistant from the substituent,

(13) L. L. Ingraham, J. Corse, G. F. Bailey, and F. Stitt, *J. Am. Chem. Soc.*, **74**, 2297 (1952).

(14) This, of course, assumes that the forces are simply harmonic, i.e., linear in displacement, and so is an approximation. Also, it will be noted that this is a classical, not quantum mechanical, idea. However, the quantum mechanical solution of the problem of describing nuclear vibrations nevertheless utilizes normal coordinates.

e.g., if substitution were made at B in the reaction  $A + BC \rightarrow AB + C$ , where AB and BC were reacting bonds and are equidistant (both terminate at atom B) from the substituent.

The net effect of a substituent on transition-state geometry can be obtained by estimating the position of the perturbed extremum along each normal coordinate as in Figure 2 and then adding the effects for all normal coordinates to find the total. Again it should be noted that, to a very good approximation, only those normal coordinates involving reacting bonds and/or nuclei near the substituent will add appreciably to the total.<sup>15</sup> The ideas just described are best explained by concrete examples, but before discussing examples, some of the qualitative ideas suggested should be examined in more detail.

The constructions in Figure 2 can be expressed algebraically. If the unperturbed extremum is placed at the origin, the assumption that the unperturbed curve is parabolic and that the perturbation is linear gives

$$V = \frac{1}{2}kX^2$$

$$P = mX + b \quad (1)$$

$$V' = \frac{1}{2}kX^2 + mX + b \quad (2)$$

where  $V$  is the unperturbed energy (solid line),  $k$  is the force constant ( $>0$  for Figure 2a,  $<0$  for Figure 2b),  $X$  is the deviation of the normal coordinate from its equilibrium value (the equilibrium geometry is usually defined as  $X = 0$  for all normal coordinates of a molecule),  $P$  is the (linear) perturbation,  $m$  the slope and  $b$  the intercept of  $P$ , and  $V'$  is the perturbed energy (dashed line). By setting the derivative of  $V'$  with respect to  $X$  equal to zero, the extremum of the perturbed curve (which is also a parabola) can be seen to be<sup>12</sup> at

$$X_{ex} = -m/k \quad (3)$$

For example, positive  $m$  gives a shorter bond for positive  $k$ , a longer bond for negative  $k$ , as shown in Figure 2. The shift in energy of the extremum is, substituting eq 3 into eq 2

$$V'_{ex} = b - m^2/2k$$

It can be seen from eq 3 that at constant  $m$  the shift of bond length is greater for smaller absolute values of  $k$ . Also the curvature or force constant is given by the second derivative of  $V$  with respect to  $X$  and can be seen to be unchanged ( $k$ ) on going from the unperturbed to the perturbed curve. It can be seen that if the perturbation were given by a smooth curve rather than a straight line, the curvature of the perturbed curve  $V'$  would be different from  $k$ , but that the *direction* of the shift  $X_{ex}$  would depend only on the slope (positive or negative) of the perturbation at  $X = 0$ , the position of the unperturbed extremum, even though the perturbation were nonlinear.

Since it is known that real molecules have potential curves that are fairly well represented by parabolas, and since molecular anharmonicities are always in the same direction, the perturbation  $P$  is likely to be a very nearly linear function. It then seems interesting to see

(15) A striking example of such a "cutoff" procedure's having negligible effects upon kinetic isotope effect calculations is given by M. Wolfberg and M. J. Stern, *Pure Appl. Chem.*, **8**, 225, 325 (1964).

results if  $P$  is linear but the potential function  $V$  somewhat anharmonic, as the next better approximation to substituent effects. In this case an anharmonic proportional to  $X^3$  should be added, giving

$$V = \frac{1}{2}kX^2 + gX^3$$

$$P = mX + b$$

$$V' = \frac{1}{2}kX^2 + gX^3 + mX + b$$

$g$  is the anharmonicity constant. Now setting derivative of  $V'$  with respect to  $X$  equal to zero, the minimum of the perturbed curve can be seen to be at

$$X_{\text{ex}} = [-k + (k^2 - 12mg)^{1/2}]/6g$$

positive  $k$  and at

$$X_{\text{ex}} = [-k - (k^2 - 12mg)^{1/2}]/6g$$

negative  $k$ . The force constant for both curves of  $V'$  is given by  $k + 6gX$  and is thus a function of  $X$ . For the unperturbed extremum ( $X = 0$ ), the force constant is  $k$ . For the perturbed extremum ( $X = X_{\text{ex}}$ ), the force constant is  $(k^2 - 12mg)^{1/2}$  for positive  $k$  and  $-(k^2 - 12mg)^{1/2}$  for negative  $k$ . This model predicts a shorter bond for positive  $m$  and  $k$ , just as the harmonic model did. The anharmonic model is more realistic, at least for bond stretching vibrations, predicting a smaller absolute value of force constant for greater  $X$  (since  $g$  is negative for bond stretching). It is expected that longer bonds (positive  $X_{\text{ex}}$ ) will both be weaker and have weaker force constants.

One very interesting point is that, apparently, anharmonicity of  $V$  should be more important in determining the change of force constant upon substitution than the nonlinearity of the perturbation, for the following reason. It can be expected that the nonlinearity of  $P$  will be in the direction that it will drop off more slowly as  $X$  increases (for bond stretching reaching an asymptotic value at the separated atoms, *i.e.*, complete bond rupture. But this direction is such that it would tend to increase the force constant for positive  $X_{\text{ex}}$  (negative  $m$ , for positive  $k$ ) and decrease force constant for negative  $X_{\text{ex}}$  (positive  $m$ , for positive  $k$ ). This direction is opposite to what is usually expected, that longer bonds are in general weaker and have weaker force constants. It must, therefore, be concluded that the anharmonicity represented by  $g$  will usually override the possible effect of nonlinearity of  $P$ !

Another point that should be justified is that the total energy of the substituent can be obtained by summation of the effects predicted for individual (harmonic) normal coordinates. By definition the individual  $P$  effects contribute additively to the energy.

$$V' = \sum_i (\frac{1}{2}k_i X_i^2 + m_i X_i + b_i)$$

The extremum of a function of more than one variable is found by setting the partial derivative of the function with respect to each variable equal to zero

$$m_i + k_i X_i = 0 \text{ (for all } i\text{)}$$

the perturbed extremum is at the position

$$(X_i)_{\text{ex}} = -m_i/k_i$$

each normal coordinate (neglecting anharmonicity), and at the point of the potential energy hyperspace with

"coordinates"  $(V'_{\text{ex}}, (X_1)_{\text{ex}}, (X_2)_{\text{ex}}, \dots, (X_i)_{\text{ex}}, \dots, (X_{3N-6})_{\text{ex}})$ , since a nonlinear molecule has  $3N - 6$  normal vibrations. The position in hyperspace can be reached by vector addition of the displacements  $(X_i)_{\text{ex}}$ . For example, with two normal coordinates (as in Figure 1) the perturbed extremum is reached by moving along  $X_1$  to  $(X_1)_{\text{ex}}$  and then perpendicular to  $X_1$  (*i.e.*, in the direction of  $X_2$ ) to a distance of  $(X_2)_{\text{ex}}$ , or equivalently along  $X_2$  first, then perpendicular to  $X_2$ . The result of such a movement to the new extremum in hyperspace can be described in three-dimensional space, of course, since the  $(X_i)_{\text{ex}}$  are known functions of the  $3N$  coordinates of the  $N$  nuclei. The effects of each normal coordinate shift upon each of the three coordinates of each nucleus can be simply added together to produce the total shift of that coordinate of that nucleus.

For the harmonic approximation, the normal coordinates associated with the perturbed extremum are exactly the same as the  $X_i$  (for the unperturbed extremum). This must be so, because all masses and force constants are unchanged. It can easily be shown that if new normal coordinates are defined as

$$X'_i = X_i - (X_i)_{\text{ex}}$$

then

$$V' - V'_{\text{ex}} = \sum_i \frac{1}{2}k_i (X'_i)^2$$

and, therefore, the  $X'_i$  are indeed normal coordinates (an alternative definition of normal coordinates being that the potential energy is proportional to the squares of the coordinates, with no cross-terms proportional to  $X_i X_j$ ).

**Rule for Predicting Geometric Changes.** The predictions of this theory can be stated concisely. Any substituent change which makes an increase (decrease) in the normal coordinate  $X$  of a molecule or transition state more difficult will lead to a perturbed equilibrium geometry in which  $X$  is decreased (increased) if the force constant for  $X$  motion is positive, but in which  $X$  is increased (decreased) if the force constant for  $X$  motion is negative.

It remains to decide whether a given substituent change will make the increase or the decrease of a given normal coordinate  $X$  more difficult. Qualitatively, it would appear reliable to consider the individual bonds which are being stretched or compressed in motion  $X$ ; further, the major effect should be upon those reacting bonds which are closest to the substituent. Nonreacting bonds which are close to the substituent could, of course, be considered but will usually be ignored in practice, and the reacting bonds will be singled out for study, as discussed in the previous section.

The valence-bond concept pictures bonds with varying amounts of covalent and ionic character. It is found, at least for diatomic molecules, that bonds between unlike atoms show greater bond energy than might be expected for "homonuclear-type" covalent bonds<sup>16</sup> (*e.g.*, as calculated for bond A-B from the geometric mean of the A-A and B-B bond energies). This "excess" bond energy can be attributed to ionic character, tending to stabilize bonds between unlike atoms, and has been used as a definition of electro-

(16) L. Pauling, "The Nature of the Chemical Bond," Cornell University Press, Ithaca, N. Y., 1960, Chapter 3.

negativity.<sup>16</sup> A reasonable extrapolation suggests that any substituent change which makes a given bond "more homonuclear", *i.e.*, lessens ionic character, will tend to make that bond more difficult to compress (and weaker). For example, in the molecule

where the atom of group B which is bonded to group A is assumed to be more electronegative than the atom of group A to which the former is bonded, it is predicted that an electron-supplying substituent would (a) if in group B tend to make both B and A more negative but have a larger effect on B than A, thus increasing ionic character and making the A-B bond more difficult to extend (and, of course, easier to compress), or (b) if in group A tend to make both B and A more negative but have a larger effect on A than B, thus decreasing ionic character and making the A-B bond more difficult to compress (and, of course, easier to extend). There is one point where electronegativities of the free atoms may not give proper results: if the substituent change also changes the charge type. The electronegativity of the atom "in the molecule" is what is needed. For example, the following substituent change

where the C-Cl and C-N bonds are reacting bonds and where Cl and N both have electronegativity 3.0 as elements, is a case where one would have to be very careful in making predictions. The charge distribution changes from the Cl substituent's being negative relative to carbon to the  $\text{N}^+(\text{CH}_3)_3$  substituent's being positive relative to carbon, even though the positive nitrogen should be more electronegative than 3.0. In such a case, it is probably best to use the acid-base properties ( $\text{N}(\text{CH}_3)_3$  being a stronger base than  $\text{Cl}^-$  in usual types of solvents), as discussed in the next paragraph. Obviously the solvent effect will be quite strong here, for polar solvation will affect little the basicity of neutral bases and decrease the basicity of negatively charged bases. The substituent effect in the gas phase could be different—even opposite—from the effect at the other extreme, say extrapolated to infinite dielectric constant. The effects for real solvents would be between the extremes, but difficult to predict theoretically. The experimental criterion of basicity can be tentatively used, but its reliability can and should be tested experimentally. Such problems as this arise only when the substituent change is unusually drastic, almost never unless one of the atoms of a reacting bond is changed.

Acid-base concepts lead to the same predictions. In the above example, B would be pictured as the basic group since it is more electronegative than A; A would be pictured as the acidic group. Supply of electrons to B should make it more basic and make the A-B bond more difficult to extend, while supply of electrons to A should make it less acidic and make the A-B bond more difficult to compress. Basicity toward a proton seems to be a good criterion<sup>8</sup> and has the advantage of simplicity: *e.g.*, absence of steric effects. Other workers have concluded<sup>17</sup> that leaving group ability is a more appropriate criterion, on the basis that leaving group ability, measured for the reaction in ques-

tion, takes account of steric effects. However, the theory described in the present paper takes account of steric effects directly by consideration of their effects on normal vibrations; it is thus more appropriate to have a measure of electrical effects which includes as little steric component as possible.

It is important to keep separate the two aspects of this theory. The first, the idea of estimating the perturbation and adding it to the unperturbed curve, is a rigorously correct approach because the perturbation (though the correct perturbation may not be linear) is *by definition* the difference between the unperturbed and the correct perturbed curve. The second aspect, the ideas that the perturbation may be considered nearly linear and that the slope of the perturbation may be estimated from ordinary bonding concepts, may have exceptions. The crucial question in the latter case is probably whether the bonding concepts which are reasonably reliable for stable molecules can also be applied to transition states. We believe and assume that they can, because as long as one is considering *differences* between substituents, there seems to be no theoretical reason that transition-state effects should differ from stable molecule effects. The only source of difficulty would seem to be if the usually long, weak reacting bonds in a transition-state structure were sufficiently different from the usually shorter, stronger bonds in stable molecules that certain predictions were made incorrectly. All indications are that there is a continuous change in bonding with bond distance,<sup>18</sup> however.

One other point should be mentioned, that the predictions made are for changes in transition-state structure, while most experimental information (rates, solvent effects, Brønsted coefficients, kinetic isotope effects) refers to the difference between reactant(s) and transition state. The correct approach would be to make predictions for all normal coordinates of both reactant(s) and transition state. However, it can be expected that *substituent* effects on nonreacting bonds will be small and also nearly the same for reactant and transition state. Evidence that this is so comes from studies of substituent and solvent effects on secondary deuterium isotope effects;<sup>19</sup> such effects are quite small. These effects could nevertheless be estimated by the present theory provided the perturbations for reactant and transition state could be predicted accurately. It is the reacting bonds which differ greatly from the bonds of the reactant(s),<sup>20</sup> being much weaker in the transition state (for bonds being broken) or much stronger in the transition state (for bonds being made). Also, since the transition-state reacting bonds will be weak in most cases, substituent effects on geometry are expected to be much larger than for ordinary, strong bonds because the curvature *k* of the potential

(18) For example, it has been shown that Badger's rule for predicting force constants from bond lengths is reliable not only for ground states of molecules, but also for excited states and even van der Waals interactions: R. M. Badger, *J. Chem. Phys.*, **2**, 128 (1934); **3**, 710 (1935); *Phys. Rev.*, **48**, 284 (1935); D. R. Herschbach and V. W. Laurie, *J. Chem. Phys.*, **35**, 458 (1961); H. S. Johnston, *J. Am. Chem. Soc.*, **86**, 1643 (1964).

(19) W. E. Buddenbaum, Ph.D. Thesis, University of Indiana, 1964; V. J. Shiner, Jr., and G. S. Kriz, Jr., *J. Am. Chem. Soc.*, **86**, 2643 (1964); G. J. Frisone and E. R. Thornton, *ibid.*, **86**, 1900 (1964).

(20) Unless the transition state is exceedingly reactant-like, in which case no substituent effect difference between reactant(s) and transition state is predicted.

(17) C. G. Swain, D. A. Kuhn, and R. L. Schowen, *J. Am. Chem. Soc.*, **87**, 1553 (1965).

function will be less for normal coordinates of weak bonds (cf. eq 3). To the extent that substituent effects on reactant bonds are very small,<sup>21</sup> this should be true except when the substituent changes one of the atoms of the bond being stretched (e.g., comparison of C-Br with C-Cl), the observed experimentally will be predicted by the combination of substituent effects on the transition state and the reactant state.

**Examples.** The above method of predicting substituent effects is in agreement with Hammond's postulate in all cases where the substituent effect is expected to be largest along the reaction coordinate—which are the only cases for which the Hammond postulate has been developed—but also, upon inclusion of perpendicular effects, is in agreement with all reasonably known experimental evidence on substituent effects. An important example is SN2 nucleophilic displacement.

A displacement reaction is illustrated in Figure 1. It can be seen that the normal coordinates of the transition state are approximately

stretching of the reacting bonds. Bending will be discussed in a later paragraph; it should be included in cases where the activated complex is made nonlinear by steric effects.<sup>22</sup> The theory predicts, for substituents at A, that electron supply will make the perpendicular normal vibration shown (A-B bond stretched) more difficult and the parallel normal vibration shown (A-B bond compressed) less difficult. The substituent effect should be determined by the bond, because it is closer to the site of substitution. The perturbation should therefore decrease the normal coordinate corresponding to the perpendicular vibration, i.e., shorten the A-B and B-C bonds (since the force constant is positive), and decrease the normal coordinate corresponding to the parallel vibration, lengthen the A-B bond and shorten the B-C bond (since the force constant is negative). In a concerted displacement, it is probable that the curvature of the potential energy surface is considerably smaller for parallel than for perpendicular motion;<sup>23</sup> the geo-shift is then expected to be determined largely by parallel motion (cf. eq 3), and the A-B bond should be lengthened while the B-C bond should be shortened by electron supply at A.<sup>24</sup> The same result should be predicted for the reverse reaction, where electron supply to A, which is then the leaving

group: that the parallel motion ought to lengthen the A-B bond and shorten the B-C bond. For substitution in entering or leaving group, the effects of parallel and perpendicular vibrations are predicted to oppose one another with respect to the bond closest to the substituted group (A-B in the above example) and to reinforce one another with respect to the bond once removed from the substituted group (B-C in the above example). It is not now possible to predict what experimental effect this interesting prediction should have, because the opposed effects occur upon the bond which should inherently be the more sensitive to substituents since it is closer to the site of substitution. It would also be possible to substitute B in the SN2 displacement reaction. In this case electron supply to B should make the perpendicular vibration shown less difficult and have a small effect on the parallel vibration. The effect on the parallel vibration should be small because it should be approximately equal but opposite for the two bonds involved in the parallel normal coordinate (making compression of A-B more difficult and stretching of B-C less difficult). If the reaction were a perfectly symmetric, concerted displacement,  $A + BA$ , the parallel effect would be exactly zero by symmetry. The substituent effect should, therefore, be determined by the effect on the perpendicular motion (and is for this reason opposite to Hammond postulate extensions), at least for fairly symmetrical transition states. For nonsymmetrical SN2 transition states, it seems likely, in analogy with Brønsted catalytic effects, that the effect would be greater on the stronger of the A-B and B-C bonds, so that the parallel motion could become important. A theoretical study of the symmetrical and nonsymmetrical cases would be very interesting. The perturbation for the former case of fairly symmetrical transition states should, therefore, increase the normal coordinate corresponding to the perpendicular vibration, i.e., lengthen the A-B and B-C bonds, and this should be the most important substituent effect. This latter effect may be quite small relative to the parallel effects in cases such as substituents at A, because the curvature of the potential energy is likely to be relatively large for perpendicular motion. The predicted pattern of substituent effects is consistent with the experimental data. For example, the chlorine kinetic isotope effect  $k_{35}/k_{37}$  for reaction of cyanide ion (1.0060), thiosulfate ion (1.0058), and water (1.0078) with *p*-chlorobenzyl chloride in 80% aqueous dioxane at 30° was found<sup>25</sup> to be largest for the weakest base water. It might be expected that the cyanide isotope effect would be smallest since it is the strongest base; however, this reaction was complicated by concurrent hydrolysis (did not exhibit precisely second-order kinetics) and the isotope effect is, therefore, an average containing some contribution from the high water isotope effect. The solvent isotope effects for  $CH_3Cl$  and  $CH_3Br$  in  $H_2O$  vs.  $D_2O$  indicate that O-C bond making is more complete for  $CH_3Cl$ .<sup>26</sup> This is a case where the substituent change involves an atom of one of the reacting bonds. The prediction for the change from Cl to Br is, in the case of the reactants, that C-X bond stretching will be made easier, i.e., that the C-Br bond will be longer than the C-Cl bond, as is known to be the case

<sup>21</sup> For example, C. G. Swain, R. F. W. Bader, R. M. Esteve, Jr., V. Griffin, *J. Am. Chem. Soc.*, **83**, 1951 (1961).  
<sup>22</sup> See C. K. Ingold, *Quart. Rev.* (London), **11**, 1 (1957).  
 The ratio of curvatures is ca. 3-5 for typical surfaces for  $H_2$ , probably the only three-center transition state for which moderate surfaces are available; see F. S. Klein, A. Persky, and R. M. J. O. Jr., *J. Chem. Phys.*, **41**, 1799 (1964). Also, it should be noted that the success of transition-state theory itself probably rests in the relative flatness of the top of the barrier for parallel motion. If it is true that the  $H_2$  surface really has a shallow basin (cf. H. and B. L. Bruner, *J. Chem. Phys.*, **42**, 4047 (1965)) giving two asymmetric transition states rather than a single symmetrical one, perpendicular curvature could be considerably weaker than parallel curvature, which gives a different prediction than the symmetrical case. Study of substituent effects in  $A + BA$  displacement reactions might, therefore, provide experimental evidence for the presence of a basin.

(25) J. W. Hill and A. Fry, *J. Am. Chem. Soc.*, **84**, 2763 (1962).  
 (26) C. G. Swain and E. R. Thornton, *ibid.*, **84**, 822 (1962).

(1.94 vs. 1.78 Å, respectively). For the transition states, it is predicted that C-X bond stretching will be easier, which implies shorter C-X and longer C-O for methyl bromide resulting from the parallel effect, and longer C-X and C-O resulting from the perpendicular effect. The parallel effect is expected to dominate, so that C-X will be slightly shorter and C-O considerably longer for methyl bromide than for methyl chloride. The transition state is expected to be more reactant-like with respect to C-O for methyl bromide and also more reactant-like for C-Br. The latter prediction was reached by comparison with the rather large substituent effect in the reactant: although C-Br is predicted to be little different in length from C-Cl in the transition state, the reactant C-Br is a great deal longer than the reactant C-Cl, and thus the methyl bromide transition state is a great deal more reactant-like, with respect to the C-Br bond, than the methyl chloride transition state is with respect to the C-Cl bond. The reaction

appears to have a shorter N-C bond for electron-withdrawing Z, since the solvent sensitivity of the rate of reaction is greater for electron-withdrawing Z (indicating greater charge destruction).<sup>27</sup> With HO<sup>-</sup> as the nucleophile instead of N<sub>3</sub><sup>-</sup>, the C-S bond is indicated to be shorter for electron-withdrawing Z since the sulfur kinetic isotope effect decreases as Z becomes more electron withdrawing.<sup>28</sup>

Another example is E2 bimolecular elimination. If only the two reacting bonds closest to the substituent are considered (and others are assumed to "follow along"), the effect of substituents Z in the elimination from a species such as β-phenylethyltrimethylammonium ion

should be predictable from the two approximate normal coordinate motions

The true normal coordinates (in particular, that for reaction coordinate motion) will involve more than three atoms, but this merely means that there will be more than one perpendicular motion involving these atoms. A better analysis of such a complex transition state would be arrived at by calculating approximately the true normal coordinates using reasonable guesses for the transition-state force constants.<sup>29</sup> The only real necessity in qualitative application of the theory is to separate the reaction coordinate motion from all perpendicular motions, since substituent effects are opposite for positive and negative force constants. In the present approximation it would be predicted that

electron-supplying Z would make the perpendicular motion as shown more difficult and make the parallel motion as shown more difficult with respect to the C-H bond and less difficult with respect to the C-C bond. We can expect, however, that in contrast to the S<sub>N</sub>2 case the effect on the parallel motion will not be zero. The effect on the C-H bond is expected to control the parallel motion because it is a σ bond; the C-C incipient π bond is not expected to change much in this motion because of the presence of the already formed C-C σ bond. It is reasonable to assume that substituent effects will always be larger on σ reacting bonds than on π reacting bonds which are equidistant from the substituent. The perturbation should, therefore, decrease the normal coordinate corresponding to the perpendicular vibration, i.e., shorten the H-C and C-C bonds, and increase the normal coordinate corresponding to the parallel vibration, i.e., lengthen the C-H bond and shorten the C-C bond. If it is assumed that the parallel shift is the more important, the C-H bond should be lengthened and the C-C bond shortened by electron supply at the central C. Since the parallel motion is expected to dominate, and since in this motion compression of the C-C bond is accompanied by extension of the C-N bond, electron supply at the central C is predicted to lengthen slightly the C-N bond. Similarly to the S<sub>N</sub>2 mechanism, increased electron supply at the base (HO<sup>-</sup> in the above example) is predicted to lengthen the O-H bond, i.e., make the transition state more reactant-like, while increased electron supply at the leaving group (N<sup>+</sup>(CH<sub>3</sub>)<sub>3</sub> in the above example) is predicted to lengthen the C-N bond, i.e., make the transition state more product-like. These predictions are in agreement with the fairly extensive experimental evidence,<sup>30</sup> which is discussed in detail in an accompanying report.<sup>2a</sup>

The S<sub>N</sub>1 mechanism presents difficulty. The evidence is that in the solvolysis of substituted cumyl chlorides, which presumably proceeds by rate-determining ionization

the solvolysis rates are more sensitive to solvent polarity (at 25°, methanol, ethanol, 2-propanol) for Z = *m*-methyl- and *p*-phenyl- and less for Z = *p*- or *m*-chloro-, *p*-carbomethoxy-, or *p*-trifluoromethyl- than for Z = H.<sup>31</sup> The data imply that the transition state occurs with more complete ionization for electron-supplying substituents. On the other hand, the present theory predicts that if the reaction coordinate motion is the stretching of the C-Cl bond, electron-supplying Z should make this motion less difficult, i.e., the C-Cl bond shorter at the transition state. It seems likely that the theory is giving a correct prediction and that the sensitivity to solvent polarity (which is very small, barely outside experimental error) does not indicate that electron supply produces a more product-like transition state. One possibility is that the transition state is made more reactant-like in geometry but has more ionic character. There is no reason why geometry and charge separation need parallel one another precisely.<sup>32</sup> The prediction of the present theory is in

ment with that of the Hammond postulate and intuitive reasoning that the very large rate increases associated with electron-supplying substituents suggest a more reactant-like transition state. The possibility of the direction of the perturbation was predicted correctly, *i.e.*, that electron supply actually makes C-Cl bond stretching more difficult, seems unlikely, although some rationalization of such a possibility has been previously given<sup>8</sup> by arguing that reacting bonds are exceedingly electron deficient in the transition state. Electron deficiency of this magnitude now seems very unlikely, and the present theory rejects the possibility of assuming that substituent effects in transition states can be predicted from the same rules which apply to stable molecules. Finally, there is the possibility that the rate-determining step is not simple ionization of the C-Cl bond. An alternative is that the transition state is practically, or even completely, ion-pair-like, with involvement of some nucleophilic center in the rate-determining step.<sup>23</sup> The nucleophile could be solvent (even the  $\pi$ -electrons of the phenyl group (an "internal" nucleophile). The mechanism would then become SN2-like and, if the perpendicular motion were to determine the substituent effect, the C-Cl bond would be predicted to be lengthened by electron-supplying Z. A more detailed discussion of the SN1-type mechanism is in preparation.<sup>2b</sup>

Very little definitive information is available about steric effects upon transition-state structure. It has been shown<sup>17</sup> that the transition state for reaction of hydroxide ion with ethylene chlorohydrin ( $x = 1$ ) is more product-like than that for tetramethylene

chlorohydrin ( $x = 3$ ). Actually proton transfer to hydroxide ion appears to be complete (prior equilibrium) for ethylene chlorohydrin. The reaction coordinate motion would be approximately

if the proton transfer were not part of this motion.<sup>17</sup> The ring strain introduced in the compression of the C-Cl bond is predicted to make the above motion more difficult, giving a more product-like transition state, for the three-membered ring formation. The calculations of steric effects in transition states of SN2 reactions<sup>22</sup> can be understood in terms of perpendicular motions. Larger alkyl groups, in the reaction

have been calculated<sup>22</sup> to give longer I-C bonds (both equal symmetry) at the transition state. In the reaction coordinate motion one I-C bond is compressed while the other is stretched; increased steric size of R should have no effect on this motion. In the perpendicular symmetric stretching motion, compression of both

bonds simultaneously should be made more difficult by increased size of R, which should, therefore, make both I-C bonds longer. Also, the calculation showed that the ICI bond angle was bent when R was not symmetric, in a direction away from the bulkiest part of R. For example, if R is neopentyl a 17.6° deviation

from 180° is predicted.<sup>22</sup> The ICI bending motion is a perpendicular motion, so it is predicted that, in comparison with the symmetric case  $\text{R} = \text{CH}_3$ , introduction of one bulky *t*-butyl substituent should make bending of the iodine atoms toward that substituent more difficult and bending away easier, giving a transition state with the I-C-I bonds bent away from the bulky substituent.

**Solvation.** In making predictions about reactions in solution, one must be concerned about the possibly large effects of the solvent upon the transition state. It cannot be doubted that in many types of reaction mechanism the solvation effect is very large; most ion-forming reactions (*e.g.*, SN2 reactions between uncharged nucleophile and substrate; SN1 reactions) do not proceed in the gas phase, and it can be shown from studies of gas-phase ions that the energy requirements for such reactions are enormous unless very strong stabilization of product ion(s) by solvation occurs. According to the present theory, solvation effects should, if strong, simply make the solvent molecule(s) a part of the transition state.

The theory proposed here assumes that the structure of the unperturbed transition state and the nature of its reaction coordinate are approximately known. It is of fundamental importance, therefore, to provide reliable criteria—experimental and theoretical—for predicting the structures of transition states. The latter is very difficult, especially for reactions involving proton transfer; the position of the proton and the timing of its transfer are difficult to decide because protons tend to be very mobile. "Solvation"<sup>17</sup> and "anthropomorphic"<sup>24</sup> rules have been proposed to help in such predictions. It should be emphasized that these rules apply to the prediction of transition-state structure, which is a completely separate (though related) problem from prediction of substituent effects.

If one accepts the predictive validity of such rules or of the present theory, they can be applied in reverse, *i.e.*, predicted substituent effects can be used to determine transition-state structure or reaction coordinate motion. Such predictions have been used to decide on the mechanism of general acid catalyzed addition of amines<sup>25</sup> and thiols<sup>26</sup> to carbonyl compounds.

It has been suggested<sup>17</sup> that proton transfers between atoms which have unshared pairs of electrons occur rapidly either before or after the transition state, so that the proton "should lie in an entirely stable potential at the transition state and not form reacting bonds nor give rise to primary hydrogen isotope effects."<sup>17</sup>

Figure 3. Approximate reaction coordinate motions for extreme types of proton transfer. (a) Concerted, unstable potential; (b) concerted, stable potential; (c) nonconcerted, unstable potential; (d) nonconcerted, stable potential. Note that motion b could not preserve the center of gravity and therefore could not be a normal coordinate for a triatomic system, but could be a normal coordinate if other atoms in the transition state also moved in such a way as to keep the center of gravity fixed.

Others have suggested<sup>36</sup> that general acid or general base catalyzed reactions should be thought of as concerted. These superficially conflicting viewpoints actually represent different mechanistic properties: the proton is in an entirely stable potential only if it does not move (relative to the center of gravity of the transition state) in the reaction coordinate motion. The proton may or may not be in a reactant-like or product-like position in the transition state; the determining factor is not the extent of proton transfer, but rather whether the reaction coordinate motion of the transition-state structure, once the transition state is reached, involves or does not involve motion of the proton. If the proton does not move in the reaction coordinate motion, it must move in one or more of the perpendicular motions, *i.e.*, in an entirely stable potential. On the other hand, a concerted, rate-determining proton transfer is one where the proton is actually bonded to a different atom in the first intermediate (or product) on the reaction path after the rate-determining transition state than it was bonded to in the first intermediate (or reactant) on the reaction path before the rate-determining transition state. Though a concerted proton transfer would be expected to involve motion of the proton in the reaction coordinate motion, it is conceivable that the other nuclei could move while the proton did not.

The extreme possibilities are illustrated in Figure 3 for a proton transfer from BH to S.

Extremes b and c seem relatively improbable, but mechanisms approaching these extremes must be considered among the spectrum of possible transition states.

**Perturbations According to the Hellmann-Feynman Theorem.** The Hellmann-Feynman theorem<sup>38</sup> gives the force acting on any nucleus of a system of electrons and nuclei as the sum of the *classical* repulsions by the other nuclei and attractions by the electrons. It therefore provides a good framework for discussing the qualitative ideas presented in previous sections and may eventually provide a quantitative estimate of perturbations. The force on nucleus  $\alpha$  in direction  $x$

is given by

$$F_{\alpha x} = \frac{\partial}{\partial x_{\alpha}} \sum_{(\beta \neq \alpha)} \frac{Z_{\alpha} Z_{\beta} e^2}{r_{\alpha\beta}} - e \int \rho E_{\alpha x} dr$$

where  $Z_{\alpha}$  is the nuclear charge of nucleus  $\alpha$ ,  $r_{\alpha\beta}$  the distance between nuclei  $\alpha$  and  $\beta$ ,  $e$  the electronic charge,  $\rho$  the total electron density, and  $E_{\alpha x}$  the electric field (in the  $x$  direction) of nucleus  $\alpha$  at the position of the electron, *i.e.*

$$E_{\alpha x} = (Z_{\alpha} e \cos \theta_{\alpha}) / r_{\alpha}^2$$

where  $\theta_{\alpha}$  is the angle between a line connecting nucleus  $\alpha$  with the electron and the  $x$  direction, and  $r_{\alpha}$  is the distance between nucleus  $\alpha$  and the electron. The density  $\rho$  is given by the sum of the squares of the wave functions for individual electrons, in the one-electron approximation

$$\rho(x, y, z) = \sum_i \psi^*(x_i, y_i, z_i) \psi(x_i, y_i, z_i)$$

By the definition of an equilibrium, all  $F_{\alpha x}$  (and  $F_{\alpha y}$  and  $F_{\alpha z}$ ) must be zero at the equilibrium geometry of any system, and this includes transition states, where the equilibrium geometry is at the energy maximum, as well as stable molecules, where the equilibrium geometry is at the energy minimum. It is interesting to consider one special case. If two systems, a perturbed and an unperturbed one, both have exactly the same nuclei and differ only in their electron densities  $\rho$ , the difference between the forces for the perturbed and unperturbed systems, both forces being evaluated at the unperturbed equilibrium geometry, is (since the unperturbed force  $F_{\alpha x}^{\text{UP}}$  is zero)

$$F_{\alpha x}^{\text{P}} = F_{\alpha x}^{\text{P}} - F_{\alpha x}^{\text{UP}} = -e \int (\rho^{\text{P}} - \rho^{\text{UP}}) E_{\alpha x} dr = -e \int \Delta \rho E_{\alpha x} dr \quad (4)$$

The electric field of the nucleus,  $E_{\alpha x}$ , is the same for both systems, and the nuclear repulsion part of the force difference exactly cancels since both forces are evaluated at the same geometry. Note that  $\Delta \rho$  is a function of three spatial coordinates, not a constant.

The above expression (eq 4) is expected to be a good approximation to the force upon nuclei involved in reacting bonds if a substituent change is made far from the reaction site. In this case the substituent change will change nuclei which are so distant from nucleus  $\alpha$  that the nuclear repulsion term will still cancel;  $E_{\alpha x}$  of course does not change unless nucleus  $\alpha$  is changed. Equation 4 is expected to be a worse approximation in cases where a nucleus close to nucleus  $\alpha$  is changed, since the nuclear repulsion terms will change. Also, if nucleus  $\alpha$  itself is changed, both the nuclear repulsion terms and  $E_{\alpha x}$  will change. However, such an approximation may still be rather good in many cases, if "similar" nuclei replace one another (*e.g.*, chlorine and bromine), because of the fact that inner shell electrons are largely localized around a single nucleus. The inner shell electrons can be thought of as simply shielding the nucleus, *i.e.*, the nuclear repulsion terms and  $E_{\alpha x}$  attractions practically cancel for inner shell electrons and the corresponding number of nuclear charges. Approximate calculations can therefore be made using eq 4, but using only the valence-shell electron densities and the (shielded) net valence-shell nuclear charges.

the very simple electrostatic expression derived for must be summed in order to derive the force for displacement according to normal coordinates, as used in the theory under discussion (cf. eq 1 and 2). To simplify notation, let the nuclear coordinates, referred to the equilibrium geometry  $x_0, y_0, z_0$  for each nucleus, be numbered consecutively,  $q_1, q_2, q_3, \dots, q_i$ , where  $q_1, q_2, q_3$  are  $(x - x_0), (y - y_0), (z - z_0)$  for nucleus 1;  $q_4, q_5, q_6$  are  $(x - x_0), (y - y_0), (z - z_0)$  for nucleus 2; etc. Then the normal coordinates can be written

$$X_j = \sum_i \ell_{ji}^{-1} q_i \text{ or } q_i = \sum_j \ell_{ij} X_j \quad (5)$$

each cartesian coordinate of each nucleus

$$\frac{\partial V}{\partial q_i} \equiv \frac{\partial V}{\partial(x - x_0)} = \frac{\partial V}{\partial x}$$

$$F_i = - \frac{\partial V}{\partial q_i} = - \frac{\partial V}{\partial x} = - e \int \Delta \rho E_i dr \quad (6)$$

In eq 4. The force for displacement according to normal coordinate  $X_j$  is

$$= - \frac{\partial V}{\partial X_j} = - \sum_i \frac{\partial V}{\partial q_i} \frac{\partial q_i}{\partial X_j} = \sum_i F_i \ell_{ij} = - e \int \Delta \rho \left( \sum_i E_i \ell_{ij} \right) dr$$

According to eq 5 and 6. Since all normal coordinates of the unperturbed system are by definition zero at the unperturbed equilibrium geometry, eq 2 gives, for the force  $m$  of the perturbation  $P$  (eq 1)

$$m = \frac{\partial V'}{\partial X_j} = -F_{X_j} \quad (7)$$

The assumption of the present theory is that  $P$  is linear, that the slope  $m$  does not change much between the unperturbed equilibrium geometry (all  $X_j$  zero) and the perturbed equilibrium geometry; if so, eq 7 gives an applicable to all geometries, not just the unperturbed equilibrium geometry. In fact, eq 7 applies to all geometries since eq 4 gives the difference between the perturbed and unperturbed forces for any nuclear geometry, and (cf. eq 2)

$$-F_i^{UP} = - \frac{\partial V^P}{\partial q_i} + \frac{\partial V^{UP}}{\partial q_i} = - \frac{\partial(V + P)}{\partial q_i} + \frac{\partial V}{\partial q_i} = \frac{\partial P}{\partial q_i}$$

It can then be seen that the quantities  $F_{X_j}$  can be defined for any geometry as long as one uses the  $\ell_{ij}$  which apply to the unperturbed equilibrium geometry (necessary since normal coordinates, and therefore  $\ell_{ij}$ , are not defined except at equilibrium extrema). The net result is that the quantities

$$m = -F_{X_j} = e \int \Delta \rho \left( \sum_i E_i \ell_{ij} \right) dr \quad (8)$$

are constant between the unperturbed equilibrium geometry and the perturbed equilibrium geometries if the assumption that the perturbation  $P$  is linear is correct, but will otherwise change somewhat.

Equation 8 not only gives a physical picture in terms of an easy-to-visualize quantity, the change in electron

probability distribution  $\Delta \rho$ , but also may provide an approximate means of estimating  $m$  values from "classical" electron density approximations, or, better, from approximate wave functions.<sup>39</sup>

A better expression for  $m$  can be written in terms of a power series for small displacements from the unperturbed equilibrium geometry ( $X_j = 0$ )

$$m = (F_{X_j})_U + \left( \frac{\partial F_{X_j}}{\partial X_j} \right)_U X_j + \frac{1}{2} \left( \frac{\partial^2 F_{X_j}}{\partial X_j^2} \right)_U X_j^2 + \dots \quad (9)$$

where the subscript U means the derivatives are evaluated at the unperturbed equilibrium geometry. Hellmann-Feynman type expressions could be written for the successive terms in eq 9; e.g.

$$\frac{\partial F_{X_j}}{\partial X_j} = - e \int \Delta \rho \left( \sum_i \ell_{ij}^2 \frac{\partial E_i}{\partial q_i} \right) dr$$

where  $i$  is summed over all coordinates of all nuclei.

In a theoretical discussion of substituent effects, it might seem as if the results would be quite different depending upon whether electron density were being supplied to (or withdrawn from) a bonding or an antibonding orbital. It might, therefore, be concluded that such simple ideas as "homonuclear character" and acid-base properties, used in previous sections for predicting substituent effects, would break down in many cases. However, the distinction between bonding and antibonding orbitals is not completely clear-cut, since the usual definition includes nuclear repulsions which are not electron energies at all. In fact, by defining "binding" orbitals as those which, when occupied, produce an attractive force tending to pull nuclei together (even though the nuclear repulsion may more than counterbalance this attractive force), and "antibinding" orbitals as those which produce a force tending to push nuclei apart, Bader and Jones<sup>40</sup> have concluded that essentially all orbitals are binding except at very small internuclear distances.

Since the Hellmann-Feynman theorem holds for all geometries of a system of electrons and nuclei, it must hold for transition states. The above arguments show that the primary assumption of the present theory, that transition states can be treated just like ordinary molecules in evaluating substituent effects, is in fact completely correct if one is calculating effects according to the Hellmann-Feynman theorem. Qualitative arguments concerning the direction of substituent effects are strongly indicated to apply in the same way to transition states as to ordinary molecules, though the validity of such qualitative arguments is not absolutely proven.

From eq 8, it is not immediately obvious why  $m$  should be nearly constant with geometry, i.e., why the perturbation should be nearly linear, for it would appear as if  $E_i$ , which changes with geometry, must produce large changes in the integral. The reason why such large changes do not occur (at least in diatomic molecules; see following section) is, of course, that  $\Delta \rho$  also changes with geometry. Though the individual densities  $\rho^{UP}$  and  $\rho^P$  must probably be redistributed a good deal upon changing the nuclear geometry, it is

(39) For an interesting discussion of the hydrogen bond and hydrogen-transfer reactions using simple wave functions with the Hellmann-Feynman theorem, see R. F. W. Bader, *Can. J. Chem.*, **42**, 1822 (1964).

Figure 4. Potential curves for HCl and HBr as calculated from the Hulburt-Hirschfelder equation, along with the difference between the curves (DIF) showing strong curvature of the DIF curve over large changes in  $r$  (though DIF is very nearly a straight line between 1.2746 and 1.4138 Å, the  $r_e$  values for HCl and HBr, respectively). It should be noted that the choice of the potential energy scale as zero for each molecule at its  $r_e$  affects only the vertical placement, and not the shape, of DIF. DIF gives the quantity which, when added to the curve for HBr, gives the curve for HCl.

entirely possible that the electron densities are polarized toward a given nucleus  $\alpha$  as it is moved away from other nuclei in nearly the amount required to offset the increased distance of nucleus  $\alpha$  by leaving the actual difference distribution  $\Delta\rho$  nearly unchanged relative to nucleus  $\alpha$ . In other words, at least two opposing effects can be expected, which will tend to make  $m$  constant with geometry (for small changes in geometry).

**Substituent Changes in Diatomic Molecules.** In order to investigate the validity of the assumption that perturbations are linear, the actual differences between potential energy curves for some diatomic molecules have been calculated and these differences checked for linearity. A computer program<sup>41</sup> has been written which calculates the energy of a diatomic molecule for interatomic distances from 0 to 5 Å at 0.1-Å intervals, and at 0.02-Å intervals between any specified pair of interatomic distances, from the potential function of Hulburt and Hirschfelder.<sup>42</sup> The experimental parameters  $\omega_e$ ,  $\omega_e x_e$ ,  $D_e$ ,  $B_e$ ,  $\alpha_e$ , and  $r_e$ , along with the reduced mass, are used to give a (supposedly) rather good prediction of the potential energy curve. The program then calculates the energy differences between all possible pairs (up to eight molecules may be examined in one computation) of molecules at the above geometries and computes the slope, intercept, and standard deviation of points for the best straight line through only the differences taken at 0.02-Å intervals. Also, the program gives the differences, calculated according to the above best straight line, for all geometries from 0 to 5 Å, along with the differences between the experimental and calculated differences.

Calculations have been made for  $H_2$ ,  $H_2^+$ , HCl,  $HCl^+$ , HBr, HI, and CH, from which some tentative conclusions can be drawn. The spectroscopic constants from Herzberg's table<sup>42b</sup> were used.

The differences are reasonably linear but tend to be concave upward, as mentioned in a previous section. These differences must, physically, approach (probably

asymptotically) constant values as the internuclear distance approaches infinity (separated atoms) and (not counting nuclear repulsions) zero (combined atoms). The former is reproduced by the program; the equation does not give correct energy results as the distance approaches zero anyway.<sup>43</sup>

The differences are precisely linear for molecules with the same nuclei, i.e.,  $H_2$  vs.  $H_2^+$  and HCl vs.  $HCl^+$ . For example, the slope for HCl minus  $HCl^+$  is 1.129 eV Å<sup>-1</sup>, and the standard deviation of points from the line (1.10 to 1.62 Å) is 0.004 eV (the equilibrium internuclear distances are 1.27 and 1.31 Å, respectively). For  $H_2$  minus  $H_2^+$ , the slope is 5.799 eV Å<sup>-1</sup>, and the standard deviation (0.74 to 1.06 Å) is 0.035 eV (equilibrium internuclear distances 0.74166 and 1.060 Å, respectively). This discovery indicates that, for merely electronic changes, without change of nuclei, the perturbations considered for substituent effects ought to be precisely linear. For complex molecules where the substituent change is made relatively far from any reacting bonds, the only effect on the reaction center should be a small change in electron density, which can be expected to produce perturbations that are much more nearly linear than the change from HCl to  $HCl^+$ .

The differences are considerably less linear for molecules of different types. For example (a particularly bad case), the slope for HI minus CH is -15.17 eV Å<sup>-1</sup>, and the standard deviation (1.10 to 1.62 Å) is 0.85 eV (equilibrium internuclear distances 1.60 and 1.12 Å, respectively). The slope changes from 46.5 to 3.5 eV Å<sup>-1</sup> between 1.10 and 1.62 Å. This is a case where the equilibrium nuclear distances are quite different, and it can be expected that such drastic changes of "substituent" will be likely to produce large deviations from linearity. A case more typical of the type of closely related structures that might be compared experimentally is HCl minus HBr (e.g., where Cl and Br are compared as leaving groups), giving: slope, 4.131 eV Å<sup>-1</sup> (1.10 to 1.62 Å), standard deviation, 0.17 eV; equilibrium internuclear distances, 1.27, 1.41 Å. The computer-calculated curves for HCl and HBr, along with their difference curve, are plotted in Figure 4.

Linearity is much better for the latter pair if the data between 1.26 and 1.40 Å are used (i.e., approximately between the equilibrium internuclear distances): slope, 4.238 eV Å<sup>-1</sup>; standard deviation, 0.016 eV. Furthermore, in cases where one of the atoms of a reacting bond is changed, transition-state perturbations must be considered relative to rather large reactant perturbations. In principle, the deviations from linearity would be expected to be of similar magnitude for reactant and transition state, and would, therefore, tend to cancel in considering, e.g., changes in reactant-like vs. product-like character in transition states.

Of course, another possible source of nonlinearity is the approximate nature of the Hulburt-Hirschfelder equation,<sup>42</sup> since the differences are taken at points fairly far removed from the equilibrium internuclear distance of at least one of each pair of molecules. The calculated energies for  $H_2$  agree with the "most likely" values from vibrational energy level analysis<sup>43</sup> to within ca.  $\pm 0.01$  eV between 0.5 and 1.4 Å, but at larger internuclear distances, agreement becomes worse:

(42) (a) H. M. Hulburt and J. O. Hirschfelder, *J. Chem. Phys.*, **9**, 61 (1941); note an error of sign in the definition of the parameter  $b$ , where the first plus sign should be a minus sign. (b) This error is also reproduced in G. Herzberg, "Spectra of Diatomic Molecules," 2nd ed., D. Van Nostrand Company, Inc., Princeton, N. J., 1950, p 102.

12 eV at 2.0 Å. The energies from the Hulburt-Heller equation have been compared with those from precise vibrational analysis for a series of electronic states of several diatomic molecules,<sup>43</sup> the average per cent difference between these values relative to the dissociation energy,  $(V_{H-H} - D_0)$ , is only about 1.5%, over the entire range of series for which vibrational data are available for molecules studied. Additional complications conceivably arise from irregularities in potential curves, e.g., if there is configuration interaction with lying excited states;<sup>44</sup> even in this case, however, effects might be expected to cancel in considerable difference between unsubstituted and substituted molecules or transition states, provided the percent change is not too drastic.

The linearity of the difference between species containing the same nuclei is surprisingly precise,<sup>45</sup> and will be further explored, especially in relation to the Hellmann-Feynman theorem (e.g., eq 4).

**Limitations of Theory.** The major problem in applying the theory qualitatively to large organic molecules is finding the reaction coordinate. It would be highly desirable to have "rules" (cf. ref 17 and 34) to aid in finding the correct reaction coordinate.

Curvature of the perturbation could be a problem, but results with diatomics indicate that, for "small" substituent changes, large curvature is unlikely. Also, the problem's existence could be investigated by studying several substituents in the same reaction; if the result is in a rational order dependent on electronic or

steric properties of the substituents, large curvature, or at least reversal of slope, could be ruled out.

For qualitative predictions, it is difficult to decide precisely about effects which may nearly cancel, i.e., where opposite effects on the same bond are predicted from two different normal vibrations. Associated with this problem is the question whether (or when) it is justifiable to assume that the curvature of the potential energy surface in the reaction coordinate (parallel) direction is considerably less than in the perpendicular directions.

Interpretation of experiments is another type of difficulty. It is not easy to design experiments which unambiguously indicate whether a certain bond is lengthened or shortened, in the transition state, by a substituent change. Solvation effects must be considered as well as effects associated with ordinary bonds. This problem is especially important in the case of the S<sub>N</sub>1 mechanism, which will be an important test for this theory.

**Conclusion.** The theory appears to give reliable qualitative predictions based on an approximate knowledge of the reaction coordinate for a reaction. It can be understood theoretically in terms of the Hellmann-Feynman theorem, and it seems justified on various qualitative grounds. We hope to explore the idea further by trying to refine the qualitative predictions (including study of substituent effects on molecular vibrations), further justify it and make quantitative predictions, and carry out experimental tests designed to uncover and explain any exceptions that may exist.

# Acetolyses of 6-Substituted *syn*-9-Benzonorbornenyl and 9-Methylbenzonorbornen-9-(*anti*- and -*syn*-)yl Arenesulfonate *anti-syn* Rate Ratios as a Test for Participation. Substituent Effects and Variation from Secondary to Tertiary Systems

Hiroshi Tanida, Yoshiteru Hata, Shiro Ikegami, and Hiroyuki Ishitobi

Contribution from Shionogi Research Laboratory, Shionogi Company, Ltd., Fukushima-ku, Osaka, Japan. Received January 3, 1967

**Abstract:** Rates in the acetolyses of 6-substituted *syn*-9-benzonorbornenyl brosylates were determined, and their substituent effects ( $k_{\text{CH}_3\text{O}}/k_{\text{NO}_2} = 43$ ) were compared to those of the *anti* brosylates ( $k_{\text{CH}_3\text{O}}/k_{\text{NO}_2} = 386,000$ ). The factor of 43 indicates the absence of homobenzylic conjugation by the aromatic ring, as demonstrated in the *anti* series, as well as efficient transmission of polar effects by the benzene moiety. The *anti-syn* rate ratios obtained by the combination of data in both series are well correlated by the modified Hammett relationship,  $\log(k/k_0) = \rho(\sigma_p^+ + \sigma_m^+)$ , with  $\rho = -3.57$ . 9-Methylbenzonorbornen-9-(*anti*- and -*syn*-)yl tosylates were prepared, and the products and rates of acetolysis were determined. Acetolysis of the tertiary *anti* tosylate led to the acetate with 98% retention and the olefin (9-methylenebenzonorbornene, 2%), while that of the *syn* led to the acetate with 67% inversion and 10% retention and the olefin (21%). The variation of *anti-syn* rate ratios from the secondary to the tertiary system is discussed in terms of participation effects.

The large effect of 6 substituents in the acetolyses of *anti*-9-benzonorbornenyl brosylates (I-OBs) (a factor of 386,000 was found between the rates of the methoxy and the nitro derivatives)<sup>1,2</sup> provides one of the most important evidences for the homobenzylic participation in these derivatives and also for the homoallylic participation in the norbornenyl derivatives, which were originally suggested by Bartlett<sup>3</sup> and Winstein,<sup>4</sup> respectively. Furthermore, our observation that the effects of the 6 substituent and the 7 substituent are additive indicates a symmetrical transition state (one of the most powerful supporting data for the 7-norbornenyl nonclassical ion).<sup>2c,5</sup> This paper deals with the rates and products in the acetolyses of 6-substituted *syn*-9-benzonorbornenyl brosylates (II-OBs) and 9-methylbenzonorbornen-9-(*anti*- and -*syn*-)yl tosylates (III-OTs and IV-OTs). Combined treatment of these results makes the Hammett approach possible for the *anti-syn* rate ratio and provides an experimental evaluation for an important suggestion in the participation theory:<sup>6</sup> tertiary carbonium ions should be stable enough to require little or no participation. Both are well-defined tests for the existence of nonclassical transition states, but not direct evidence for nonclassical ions.

**Preparations.** The syntheses and properties of the various types of II-OH used in this study were already reported.<sup>2b</sup> Their brosylates II-OBs were prepared

by standard procedures and gave satisfactory analysis. Addition of methyllithium to 9-benzonorbornenol produced a mixture composed of 88% III-OH : 12% IV-OH. These were isolated in the pure state

by a combination of recrystallization and chromatography. The structural characterization was made comparison of the chemical shifts of the 9-methyl group ( $\tau$  8.96 in III-OH and 8.73 in IV-OH) and also by presence of an internal interaction between the hydroxyl group and the  $\pi$  electrons of the benzene ring in infrared spectrum of IV-OH. Since the *p*-nitrozoates of the tertiary III-OH and IV-OH were formed

Winstein, M. Shatavsky, C. Norton, and R. B. Woodward, *J. Am. Chem. Soc.*, **77**, 4183 (1955), have reported  $k_1$  ( $205^\circ$ ) =  $8.40 \times 10^{-8}$  sec<sup>-1</sup>,  $\Delta H^\ddagger$  =  $35.7$  kcal,  $\Delta S^\ddagger$  =  $-3.5$  cal/deg. With the ratio  $k_1(\text{OTs}) = 2.90$ ,  $k_1$  of the brosylate at  $77.6^\circ$  is calculated as  $1.86 \times 10^{-10}$  sec<sup>-1</sup>.

very inert under solvolysis conditions, the *syn*- of their tosylates were undertaken. Reactions of chlorides with the lithium salts of III-OH and in tetrahydrofuran (prepared by treatment with lithium) were successful for this purpose. As reference compound, 7-methylnorborn-7-yl tosylate (I) was similarly prepared from 7-methylnorborn-1-ol.<sup>8</sup>

**Acetolysis of *syn*-9-Benzonorbornenyl Brosylates and Stereoelectronic Effects on the *anti*-*syn* Rate Ratios.** The rates of acetolysis were determined by standard procedures, and in each case the theoretical infinity titer was obtained. Table I summarizes the rates from the series of IIa-e-OBs and, for comparison, the rates of I-OBs calculated by Arrhenius plots, the rates of I-OBs, and the *anti*-*syn* rate ratios.

Acetolysis of II-OBs leads to completely rearranged, nonstereospecific, products. The reaction in acetone (40:60 vol. %) with added NaHCO<sub>3</sub> for 1 week yielded a mixture consisting of 98.6% benzo[3,4]bicyclo[3.2.0]heptenol (VIa) and 1.4% *syn* isomer VIb. The structural determination of

product. In contrast, acetolysis of 7-norbornyl brosylate yields a mixture containing 91% unrearranged acetate, 7% *anti*-2-bicyclo[3.2.0]heptanol, and 2% bicyclo[3.2.0]hept-2-ene.<sup>11</sup> Therefore, it should be considered that the formation of a stabilized benzylic carbonium ion, probably with participation of the 1,2-carbon bond,<sup>12</sup> provides a strong driving force for the rearrangement in the reaction of IIa-e-OBs.

Compared to a factor of 386,000 in the I series, the rate range from the methoxy to the nitro in the II series was only 43. This substantiates the fact that significant participation (homobenzylic conjugation) such as in the acetolysis of I is absent in that of II. However, the factor of 43 is too large for a simple electrostatic interaction. An example of similar reactions involving only inductive effects is the acetolysis of 5-substituted 2-indanyl brosylates. These materials were synthesized<sup>13</sup> and solvolyzed. The rate constants are listed in Table II. The corresponding rate factor is only 8. This value is normal, because the inductive effect should decrease rapidly when going through saturated bonds.<sup>14</sup> Therefore, it may be argued by the factor of 43 (the *syn* effect) that polar effects of the benzene ring are transmitted with considerable efficiency by the  $\pi$  cloud to the reaction center. Consequently, the rate change in the I series involves two factors: participation by the aromatic  $\pi$  system and this *syn* effect. By eliminating

(11) S. Winstein, F. Gadiant, E. T. Stafford, and P. E. Klinedinst, Jr., *J. Am. Chem. Soc.*, **80**, 5895 (1958).

(12) A referee pointed out the possibility of this effect. We appreciate his comment and infer on this basis that, if the difference in steric factors between II-OBs and 7-norbornyl-OBs could be neglected in controlling the departure of the brosyl groups, the absence of the participation would result in a rate of IIe-OBs considerably slower than that of 7-norbornyl-OBs because of polar effects by the nitrobenzene moiety in IIe-OBs.

(13) Syntheses and properties will be reported in N. Inamoto, S. Masuda, K. Tori, K. Aono, and H. Tanida, *Can. J. Chem.*, in press.

products and their acid-catalyzed rearrangements separately reported.<sup>9</sup> However, since a control experiment showed that VIb epimerized slowly to the less hindered VIa<sup>10</sup> under the hydrolysis conditions it is not clear whether the above product ratios complete kinetic control. It is theoretically anticipated that, despite the absence of rate enhancement (or of 1.05 relative to 7-norbornyl brosylate), the series of IIe-OBs showed predominant rearrangement—a rough vpc showed the absence of the retention

this effect, the *anti-syn* rate ratio should represent the rate change due only to the participation. Table I shows that the ratio changes from a factor of  $3.9 \times 10^{-4}$  for the methoxyl derivative to 4.4 for the nitro

derivative. The plots of  $\log(k_{anti}/k_{syn})$  vs.  $1/2(\sigma_p^+ + \sigma_m^+)$  yield a reasonably good correlation with  $\rho = -3.57$  (Figure 1). This is similar to the correlation of  $\log k_{anti}$  by  $1/2(\sigma_p^+ + \sigma_m^+)$  where  $\rho = -5.10$ .<sup>2b,c</sup> By simple  $\sigma^+$  plots the chloro and nitro derivatives are

Table II. Acetolyses of 5-Substituted 2-Indanyl Brosylates

distinctly below the line defined by the methoxy, methyl, and hydrogen points. Other Hammett plots attempted in a previous paper<sup>2b</sup> provided unsatisfactory correlations. The large negative  $\rho$  value ( $-3.57$ ) thus obtained indicates unequivocally that the amount of participation and the magnitude of the *anti-syn* rate ratio increase as activating substituents are introduced into the aromatic ring, whereas they reverse by introducing deactivating substituents. Figure 1 also suggests that, with a more positive  $\sigma^+$  value than the nitro, the rate of a *syn* derivative would be greater than that of the corresponding *anti*. This was proven by the rates of 6,7-dinitro derivatives where  $k_{anti} = 1.40 \times 10^{-5}$  and  $k_{syn} = 9.21 \times 10^{-5}$  sec<sup>-1</sup> at  $198.5 \pm 0.4^\circ$  in a water-acetic acid (20:80 vol. %) mixture. It is conceiv-

able that the highly electron-deficient group (dinitrobenzene) electrostatically attracts the leaving sulfonyloxy anion on the same side.

Acetolysis of 9-Methylbenzonorbornen-9-(*anti*- and *syn*)-yl Tosylates (III-OTs and IV-OTs) and Variation of the *anti-syn* Rate Ratios from Secondary to Tertiary Systems. Table III lists the rates from acetolysis of III-OTs, IV-OTs, and V-OTs, with other pertinent data.

The acetolysis of III-OTs resulted in a mixture consisting of 98% III-OAc and 2% 9-methylenebenzonorbornene (VII). In contrast, the reaction with IV-OTs

yielded a mixture consisting of 67% III-OAc, 10% IV-OAc, and 21% VII. These products were recovered unchanged under the reaction conditions and were verified to be the products of kinetically controlled solvolyses. Absence of the IV-OAc (inversion product) from III-OTs was demonstrated by vpc in amounts

ter than 0.3% yield. It should be noted that this rate and the formation of VII less than that from OTs, with the *anti-syn* rate ratio by a factor of 493, indicate some amounts of participation in the acetolysis of I-OTs.

Without firm experimental supporting evidence, it has been widely suggested that,<sup>6,15-18</sup> as a cationic center made more and more stable by changing a secondary carbon into a tertiary system, both the amount of participation and the magnitude of the *anti-syn* (or *exo-endo*) rate ratio in the norbornyl derivatives, which has been attributed to carbon participation,<sup>19</sup> should be expected to drop. Following this suggestion, Brown and his associates extensively studied the solvolysis of the secondary and tertiary esters or halides of the 2-norbornyl<sup>15a-c</sup> and 2-benzonorbornenyl<sup>17</sup> systems and observed no significant changes in the *exo-endo* rate ratios between the secondary and tertiary derivatives. These results have been interpreted in an alternative way as the absence of significant contribution on participation (Brown<sup>15,17,20</sup>), or a fortuitous cancellation of increasing steric assistance in the primary systems with decreasing carbon participation (Ceyer<sup>21</sup>). Since participation of the  $\pi$  electrons of *anti*-7-norbornenyl and *anti*-9-benzonorbornenyl systems is the greatest on record and its existence is supported by even nonclassical nonsupporters,<sup>20b</sup> the present rate results should help to clarify this problem. As shown in Table III, the *anti-syn* rate ratios changed by a factor of 2400 to 493 with the transformation from the secondary to the tertiary system. This change in the rate ratio would be predicted for a major decrease in carbon participation accompanied by increasing stability of the cationic center. However, the change between both systems is only a factor of 4.9. Accordingly, it should be concluded that, even though chemically sound, the above suggestion is too insensitive as a test of participation when compared with the effect of substituent effects as mentioned above.

A methyl group at a carbonium center stabilizes the electron-deficient species because of its ability to supply electrons to the electron-deficient center. The greater electron deficiency, the greater the contribution of the substituent. Brown has observed a relatively constant factor of 55,000 for the effect of  $\text{CH}_3:\text{H}$  (the contribution of methyl) in many representative isopropyl and *t*-butyl systems

$$(\text{CH}_3)_3\text{CX}:(\text{CH}_3)_2\text{CHX} = 55,000 \text{ at } 25^\circ$$

$$\text{C}_6\text{H}_5(\text{CH}_3)_2\text{CX}:\text{C}_6\text{H}_5(\text{CH}_3)\text{CHX} = 1800$$

as a factor of 1800 in *t*-cumyl chloride and  $\alpha$ -phenylbenzyl chloride. This indicates that the methyl substituent is making a much smaller contribution to the

resonance-stabilized  $\alpha$ -phenylethyl transition state than to the less stable isopropyl transition state.<sup>15d,22</sup> Therefore, the small  $\text{CH}_3:\text{H}$  factor of 18,000 relative to 86,700 (Table III) is in line with the presence of participation of the *anti* series (I and III), but the difference is, here again, too small to demonstrate this procedure as a competent test for participation.

The  $\text{CH}_3:\text{H}$  factor of  $5.1 \times 10^7$  for the 7-norbornyl cation is very large. This reveals that the cation makes an enormous demand on substituents for further stabilization. The existence of great participation in this system is consistent with this finding. We are currently investigating the substituent effects on the solvolysis of 7-phenylnorborn-7-yl derivatives, with the expectation that an extraordinarily large  $\rho$  value will be obtained as a semiquantitative expression of the enormous electron demand.

## Experimental Section<sup>23</sup>

**Kinetic Measurements.** The acetolysis conditions and procedure were the same as previously reported.<sup>2b</sup>

**9-Methylbenzonorbornen-9-(*anti*- and -*syn*-ol (III-OH and IV-OH).** A. Methyl iodide (8.52 g) in 20 ml of ether under a nitrogen atmosphere was added to a suspension of 830 mg of lithium metal in 30 ml of boiling ether. After stirring for 1 hr, a solution of 6.32 g of 9-benzonorbornenone in 40 ml of benzene was added and the mixture refluxed for 1 hr. The mixture was poured into a saturated  $\text{NH}_4\text{Cl}$  solution, extracted with ether, and dried. Evaporation of the ether gave 6.93 g of a 88:12 mixture of III-OH and IV-OH. Recrystallization from *n*-hexane yielded pure III-OH with mp 108–108.5°. Elution chromatography of the mother liquor on Florisil gave a second yield of III-OH as well as IV-OH with mp 92.2–93.2°. The yields were 4.67 g of III-OH and 0.62 g of IV-OH.

*Anal.* Calcd for  $\text{C}_{12}\text{H}_{14}\text{O}$ : C, 82.72; H, 8.10. Found for III-OH: C, 82.62; H, 8.05. For IV-OH: C, 82.59; H, 8.08.

B. Treatment of 9-benzonorbornenone with methylmagnesium iodide in ether resulted in the exclusive formation of III-OH. The yield was 88%.

**Tosylates of III-OH and IV-OH.** A. **III-OTs.** To a solution of 1.05 g of III-OH in 30 ml of tetrahydrofuran, a solution of 4.4 ml of 15% *n*-butyllithium-*n*-hexane solution was added dropwise at 5–10° under a nitrogen atmosphere. After stirring for 30 min, a solution of 1.34 g of tosyl chloride in 10 ml of tetrahydrofuran was added at 5–7° and the mixture stirred for 3 hr. The tetrahydrofuran was evaporated; the residual syrup was dissolved in ether, washed with water, dried, and evaporated. The crystals obtained were recrystallized from *n*-hexane to yield 1.57 g (80%) of III-OTs with mp 90–91°.

*Anal.* Calcd for  $\text{C}_{13}\text{H}_{16}\text{O}_2\text{S}$ : C, 69.48; H, 6.14. Found: C, 69.27; H, 6.35.

B. **IV-OTs**, mp 74.8–75.8°, was similarly obtained.

*Anal.* Found: C, 69.56; H, 6.15.

**7-Methylnorborn-7-yl tosylate**, mp 48–49°, was similarly prepared from 7-methylnorbornan-7-ol, mp 98–99° (lit.<sup>9</sup> 97–98°).

*Anal.* Calcd for  $\text{C}_{13}\text{H}_{18}\text{O}_2\text{S}$ : C, 64.25; H, 7.19. Found: C, 64.44; H, 7.21.

**9-Methylenbenzonorbornene.** Methyltriphenylphosphonium bromide (7.14 g) was added to a stirred solution of 12.6 ml of 15% *n*-butyllithium-*n*-hexane in 60 ml of ether at approximately 23° over a 15-min interval. The mixture was stirred for an additional

2 hr until a dark orange solution was obtained. To this a solution of 3.16 g of 9-benzonorbornenone in 50 ml of tetrahydrofuran was added and the mixture refluxed for 10 hr. The tetrahydrofuran was evaporated; the residue was extracted with ether, washed with water, dried, and evaporated, leaving an oil. Distillation of the oil followed by elution chromatography over Florisil yielded 1.1 g (35%) of 9-methylenebenzonorbornene, bp 76–78° (5 mm),  $n_D^{20}$  1.5680.

*Anal.* Calcd for  $C_{12}H_{12}$ : C, 92.26; H, 7.74. Found: C, 92.44; H, 7.88.

**6,7-Dinitrobenzonorbornen-9-anti-ol.** To a solution of 656 mg of 6-nitrobenzonorbornen-9-anti-ol acetate<sup>1b</sup> in 8 g of 98%  $H_2SO_4$  was added a mixture containing 225 mg of fuming  $HNO_3$  ( $d$  1.5) and 450 mg of 98%  $H_2SO_4$  at about 0°. The usual work-up gave 480 mg of the crude dinitro acetate. This compound was hydrolyzed by heating for 4 hr on a steam bath in a solvent composed of 70 ml of 20%  $H_2SO_4$  and 30 ml of dioxane. The work-up yielded 6,7-dinitrobenzonorbornen-9-anti-ol, mp 130–131°.

*Anal.* Calcd for  $C_{11}H_{10}O_4N_2$ : C, 52.80; H, 4.03; N, 11.20. Found: C, 52.96; H, 4.26; N, 10.81.

The brosylate was prepared by the standard procedure and had mp 195°.

*Anal.* Calcd for  $C_{17}H_{14}O_7SBrN_2$ : C, 43.51; H, 2.79; N, 5.97. Found: C, 43.54; H, 2.85; N, 6.03.

**6,7-Dinitrobenzonorbornen-9-syn-ol**, mp 148–149°, was similarly prepared by the nitration of 6-nitrobenzonorbornen-9-syn-ol acetate,<sup>1b</sup> followed by hydrolysis.

*Anal.* Calcd for  $C_{11}H_{10}O_4N_2$ : C, 52.80; H, 4.03; N, 11.20. Found: C, 52.88; H, 4.09; N, 11.03.

The acetate had mp 216–217°.

*Anal.* Calcd for  $C_{13}H_{12}O_6N_2$ : C, 53.43; H, 4.14. Found: C, 53.42; H, 4.02.

The brosylate had mp 204–205°.

*Anal.* Calcd for  $C_{17}H_{14}O_7SBrN_2$ : C, 43.51; H, 2.79. Found: C, 43.46; H, 2.84.

**Vpc analyses of solvolysis products** were carried out on a Hitachi gas chromatograph Model F-6, equipped with a 1 × 3 mm stainless steel column packed with 10% SE 30 on 60–80 mesh Chromosorb W. Helium was used at a pressure of 1 kg/cm<sup>2</sup> as a carrier gas. Retention times of *anti*- and *syn*-2-benzo[3,4]bicyclo[3.2.0]heptan-2-ol at 150° were 20.2 and 23.1 min, respectively. Those of 9-methylenebenzonorbornene, III-OAc, and IV-OAc at 120° were 9.5, 38.4, and 35.3 min, respectively.

## Proximity Effects. XLVI. Stereospecific Synthesis of *cis*- and *trans*-4-Phenylcyclooctanol<sup>1</sup>

Arthur C. Cope,<sup>2</sup> Michael A. McKervery,<sup>3a</sup> and Ned M. Weinshenker<sup>3b</sup>

Contribution from the Department of Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139. Received January 25, 1967

**Abstract:** The stereospecific synthesis of *cis*- and *trans*-4-phenylcyclooctanol *via* transannular reactions involving oxygen-bridged ring precursors is described. A number of alternative paths involving cyclizations with lead tetraacetate, mercuric acetate, and mercuric oxide and iodine have been investigated and several products have been identified. An improved synthesis of *cis*-5-phenylcyclooctanol is described.

Previous papers in this series describe the synthesis of cyclooctane derivatives as part of a general study of proximity effects and transannular reactions in medium-ring compounds.<sup>4</sup> Our interest in such systems includes the use of transannular reactions to develop convenient stereospecific routes to the less accessible phenylcyclooctanols. The general approach was to synthesize cyclooctyl compounds with suitably constituted oxygen bridges which could subsequently be severed by hydrogenolysis. Thus, in principle, bridge scission<sup>5</sup> of 1-phenyl-9-oxabicyclo[4.2.1]nonane (**1a**) and 1-phenyl-9-oxabicyclo[3.3.1]nonane (**1b**) at the benzylic carbon-oxygen bonds would give rise to 4-phenylcyclooctanol and 5-phenylcyclooctanol, respectively. The utility of this approach depends on the hydrogenolysis occurring exclusively at the benzylic position and on the ring-opening process being stereo-

specific. There was ample evidence that the former condition would hold; the latter condition appeared less certain. As an initial exploration of this idea this paper describes the synthesis and hydrogenolysis of the cyclic ethers **1a** and **b**.

Many examples of the formation of cyclic ethers on treatment of steroidal alcohols with lead tetraacetate have been reported.<sup>6</sup> The reaction has been extended to saturated acyclic,<sup>7</sup> unsaturated acyclic,<sup>8</sup> and saturated bicyclic<sup>9</sup> alcohol systems. The cyclic ethers formed usually have been five membered rather than six membered although in some cases mixtures of the two have been isolated. For example, treatment of cyclooctanol with lead tetraacetate in benzene gave 9-oxabicyclo[4.2.1]nonane; no detectable amount of the 1,5 isomer could be found in the product.<sup>10</sup> Under similar conditions, 1-methylcyclooctanol gave a mixture (1:3) of 1-methyl-9-oxabicyclo[4.2.1]nonane and 1-methyl-9-oxabicyclo[3.3.1]nonane.<sup>10</sup> Thus, introduction of a methyl group may alter the conformation of the cyclooctane ring so as to favor the formation of the 1,5 over

the 1,4 oxide. Other reagents which effect cyclic ether formation from monohydric alcohols include mercuric oxide and iodine, lead tetraacetate and iodine, silver oxide and bromine, and N-iodosuccinimide. These reactions have been reviewed by Heusler and Kalvoda.<sup>11</sup> Bordwell<sup>12</sup> has described the mercuriation of 4-cycloocten-1-ol with mercuric acetate in the presence of sodium acetate. Reduction of the resulting 5-acetoxymercuri-9-oxabicyclo[4.2.1]nonane with sodium borohydride gave 9-oxabicyclo[4.2.1]nonane uncontaminated by the [3.3.1] isomer.

In the present study, 1-phenyl-4-cycloocten-1-ol (2), prepared from 4-cycloocten-1-one and phenylmagnesium bromide, was treated with lead tetraacetate in boiling chloroform for 10 hr. Gas chromatographic and infrared analysis of the crude product indicated the

presence of a saturated acetate (97%) in addition to two minor components (3%). One of the minor components<sup>13</sup> appeared to be a mixture of phenylcyclooctadienes formed presumably by dehydration of the starting alcohol during the reaction or during the gas chromatographic analysis. The saturated acetate fraction, which could be obtained pure by distillation, had significant infrared absorption<sup>14</sup> at 1730, 1070, and 1025  $\text{cm}^{-1}$ . It was further resolved by gas chromatography into the isomers 3a and b (present in about equal amounts). It was not necessary at this stage to determine the stereochemistry of the acetoxy substituent since the asymmetry at this position was to be removed in a subsequent step. It follows however from analogy with a similar reaction with 4-cycloocten-1-ol.<sup>15</sup> The

acetate mixture was reduced with lithium aluminum hydride to give a mixture of the secondary alcohols 4a and b (approximately equal amounts). Oxidation with chromium trioxide in pyridine gave the corresponding ketones 5a and b. Wolff-Kishner reduction of the ketone mixture afforded the ethers 1a (60%) and b (40%) in 95% yield. Partial separation of the ether mixture was achieved by crystallization from pentane at  $-78^\circ$ . Isomer 1b separated as a crystalline solid, mp  $47-47.5^\circ$ , and the filtrate, which was enriched (70-75%) with isomer 1a, could be further purified by chromatography on alumina. In this way 1a was obtained 90% isomerically pure.

The method of oxymercuration followed by reduction is of synthetic value for ethers, alcohols, and lactones.<sup>12,16</sup> This route was chosen in an attempt to increase the amount of the [4.2.1] isomer initially present in the mixture. Addition of the mercuri group was also chosen in the hope that a crystalline product would be obtained. Mercuriation of 1-phenyl-4-cycloocten-1-ol with mercuric acetate in the presence of sodium acetate proceeded rapidly at room temperature to give a mixture of 1-phenyl-5-acetoxymercuri-9-oxabicyclo[4.2.1]nonane (6a) and 1-phenyl-4-acetoxymercuri-9-oxabicyclo[3.3.1]nonane (6b) as a crystalline solid. The isomeric composition could not be determined directly but sodium borohydride reduction<sup>12</sup> of the mixture gave the ethers 1a (70%) and b (30%). In addition it was found that fractional crystallization of 6 gave the [4.2.1] isomer 6a as the less soluble fraction and in this way the purity of this isomer was increased to >95%. Reduction of 6a with sodium borohydride gave 1a in 62% yield. The formation of the acetoxymercuri ethers 6a and b indicates that a functional group such as hydroxyl can participate in a transannular reaction as an internal nucleophile. The stereochemistry of the oxymercuration products was not determined but the relative configurations of the oxygen atom and the acetoxymercuri substituent in the product will be *trans* as shown on the basis of the normal *trans* addition to the olefinic bond.<sup>12,16-18</sup>

We also undertook a study of the photochemically induced reaction of 1-phenylcyclooctanol with mercuric oxide and iodine to determine whether the 1-phenylcyclooctyloxy radical would undergo a transannular rearrangement of the type observed in the photochemical decomposition of 1-methylcyclooctyl hypochlorite.<sup>19</sup> The action of such reagents as mercuric oxide and iodine or mercuric acetate and iodine on monohydric alcohols may also involve transannular hydrogen abstraction through the decomposition of the *in situ* produced hypiodites. Unlike hypochlorites, these hypiodites have not been isolated or characterized.<sup>20</sup> A complex mixture of products was obtained on ir-

yield. The configuration of the acetoxy substituent in both isomers was established to be as shown: A. C. Cope and M. A. McKervey, unpublished results.

(13) Comparison based only on retention time on gas chromatography.

(14) 9-Oxabicyclo[4.2.1]nonane and 9-oxabicyclo[3.3.1]nonane have distinguishing infrared bands at 1065 and 1022  $\text{cm}^{-1}$ , respectively.

(15) We observed initially that the reaction of 4-cycloocten-1-ol with lead tetraacetate gave a mixture of the acetoxy ethers i and ii in high

radiation of 1-phenylcyclooctanol (7) in cyclohexane containing mercuric oxide, iodine, and calcium carbonate. Two of the major products, isolated in ~30% yield by chromatography and distillation, were identified as the desired ethers 1a and b. 8-Iodo-1-phenyloctan-1-one (8), the product of the type of ring-opening rearrangement predominating in the decomposition of five- and six-membered cyclic tertiary hypohalites,<sup>21,22</sup> was also isolated. Thus a total of at least 30% of the photochemical reaction proceeded *via* transannular radical rearrangements involving both the 4 position (~15%) and the 5 position (~15%) of the cyclooctane ring.<sup>23</sup> Three methods for the preparation of the ethers 1a and b were thus in hand.

In order to establish the stereochemistry of the hydrogenolysis of 1a and b, a number of points were considered. First, we expected cleavage to occur exclusively at the benzylic position and indeed when the hydrogenolysis was carried out in ethanol containing a trace of perchloric acid<sup>24</sup> using palladium as catalyst the ethers gave products which were clearly the desired secondary alcohols. Second, the availability of *cis*- and *trans*-5-phenylcyclooctanol from another synthetic sequence<sup>25</sup> provided a direct check on the stereospecificity of hydrogenolysis of isomer 1b. This isomer gave an alcohol 9b which was identical in melting point and infrared spectrum with a sample of *cis*-5-phenylcyclooctanol prepared by Cope and Kinnel.<sup>25,26</sup> The hydrogenolysis proceeds therefore with inversion of configuration at the benzylic carbon atom.<sup>27</sup> A similar reaction with isomer 1a gave a crystalline alcohol, mp 79–80.5°, to which we assign the *cis* configuration 9a. For comparative purposes 9a was converted to *trans*-4-phenylcyclooctanol by tosylation, inversion with tetraethylammonium acetate, and reduction of the resulting *trans*-4-phenylcyclooctyl acetate with lithium alu-

minum hydride. The *trans* alcohol<sup>28</sup> thus obtained, mp 63–64.5°. The infrared spectra of the *cis* and alcohols showed significant differences; in particular the *cis* isomer had a strong band at 985 cm<sup>-1</sup> was absent in the spectrum of the *trans* isomer.<sup>29</sup> Iodine aluminum hydride reduction of 4-phenylcyclooctanone gave a crystalline product, mp 44–52°, which shown by infrared to be a mixture of the *cis* and alcohols.

### Experimental Section<sup>30</sup>

**1-Phenyl-4-cycloocten-1-ol (2).** A solution of 4-cycloocten-1-ol (25 g) in anhydrous ether (100 ml) was added dropwise 45 min to a stirred solution of phenylmagnesium bromide prepared from bromobenzene (34.8 g) and magnesium (5.3 g) in anhydrous ether (250 ml). The mixture was stirred for an additional 15 min and was then treated with saturated ammonium chloride solution. The solids were removed by filtration, and the solvent was evaporated to give a yellow oil (41 g). A 34-g fraction was collected through a 6-in. Vigreux column to yield a main fraction of (75.7%) of the pure alcohol, bp 106–109° (0.02 mm).

*Anal.* Calcd for C<sub>11</sub>H<sub>18</sub>O: C, 83.12; H, 9.01. Found: C, 83.30; H, 8.97.

**1-Phenyl-5-acetoxy-9-oxabicyclo[4.2.1]nonane (3a) and 1-4-acetoxy-9-oxabicyclo[3.3.1]nonane (3b).** Commercial lead tetraacetate<sup>31</sup> (20 g) was dried at 25° (0.05 mm) for 1 hr. A solution of 1-phenyl-4-cycloocten-1-ol (2) (5 g) in reagent grade chloroform (50 ml) was added to the lead tetraacetate, and the mixture was under reflux for 10 hr. (In larger scale preparations it was necessary to use mechanical stirring and to add the alcohol slowly to a solution of lead tetraacetate in chloroform as the initial reaction was exothermic.) The reaction mixture was cooled and excess lead tetraacetate was destroyed by the addition of ethylene glycol (10 ml). The solution was poured into a large volume of water and a chloroform layer was separated and washed with two 5-ml portions of 10% sodium thiosulfate solution and water. After drying the solvent was removed to give a viscous oil (6.55 g). Distillation yielded 5.05 g (77%) of a mixture of the acetoxy ethers 3a and 3b, bp 131–135° (0.22 mm). Gas chromatographic analysis on a 0.25 in. i.d. 5% XF-1150 column at 180° showed the presence of two isomers in the ratio 49.5:50.5. A sample from a similar preparation was redistilled at 135–136° (0.4 mm) and was an 80:20 mixture of 3a and 3b. The infrared spectrum showed no olefinic or hydroxyl absorption but had significant bands at 1730, 1070, and 1025 cm<sup>-1</sup>. In all of preparations the yields ranged from 60 to 84% after distillation.

*Anal.* Calcd for C<sub>14</sub>H<sub>20</sub>O<sub>3</sub>: C, 73.82; H, 7.74. Found: C, 74.13; H, 7.80.

**1-Phenyl-5-hydroxy-9-oxabicyclo[4.2.1]nonane (4a) and 1-4-hydroxy-9-oxabicyclo[3.3.1]nonane (4b).** A solution of the acetoxy ether mixture 3a and b (20 g) in anhydrous ether (50 ml) was added dropwise to a stirred slurry of lithium aluminum hydride (2.25 g) in anhydrous ether (200 ml). The mixture was stirred

(28) Our stereochemical assignments were supported in the following way: reaction of *trans*-4-phenylcyclooctanol with lead tetraacetate gave the ether 1a as the major product whereas the *cis* isomer gave a mixture of products which contained no detectable amount of 1a. A similar reaction with *trans*-5-phenylcyclooctanol gave the ether 1b in high yield whereas the *cis* isomer gave compound iii as the major product. A. C. Cope, R. B. Kinnel, M. A. McKerver, and N. M. Henker, unpublished results.

(29) Both isomers had identical retention times on all the gas chromatography columns available; the corresponding acetates and fluoroacetates were also inseparable by gas chromatography. A melting point diagram for the alcohols showed that less than 1% of either isomer in a mixture produced a measurable depression in melting point (see Experimental Section).

(30) Melting points were taken on a Thomas-Hoover melting point apparatus and are uncorrected; boiling points are uncorrected. Chromatographic analyses were carried out using an F & M Model 400 gas chromatograph. Nmr spectra were recorded on a Varian A-60 instrument. Microanalyses were performed by Dr. Nagy and his associates. Except as noted the drying agent used was sodium sulfate and solvents were removed under reduced pressure.

(23) About 60% of the decomposition of 1-methylcyclooctyl hypochlorite proceeded *via* transannular rearrangement involving both the 4 position (35%) and the 5 position (24%); see ref 19.

(24) In the absence of perchloric acid the hydrogenolysis proceeds much more slowly.

(25) A. C. Cope and R. B. Kinnel, *J. Am. Chem. Soc.*, **88**, 752 (1966).

(26) The earlier synthesis involved a tedious fractional crystallization of a mixture of *cis*- and *trans*-5-phenylcyclooctyl 3,5-dinitrobenzoates, the *cis* isomer being the less soluble in chloroform-ethanol.

(27) For a discussion of the stereochemistry of hydrogenolysis of some benzyl ethers see S. Mitsui, Y. Senda, and K. Konno, *Chem. Ind. (London)*, 1354 (1963), and references contained therein.

itional 1.5 hr and was then treated cautiously with cold water. Precipitate was separated and the ether solution evaporated to give 16.8 g (100%) of a viscous oil which partially solidified on cooling. The infrared spectrum of this material showed strong C=O absorption and the absence of acetate absorption. Gas chromatographic analysis (10-ft, 10% XF-1150 column at 198°C) showed that 4a and b were present in about equal amounts. A sample was recrystallized several times from benzene-pentane and then sublimed at 70° (0.1 mm). The highest melting point observed was 73–74.5°; gas chromatography showed that this oil still contained both isomers.

Calcd for  $C_{14}H_{18}O_2$ : C, 77.03; H, 8.31. Found: C, 76.8; H, 8.46.

**enyl-5-oxo-9-oxabicyclo[4.2.1]nonane (5a) and 1-Phenyl-4-oxabicyclo[3.3.1]nonane (5b).** A solution of the alcohol 4a and b (23.3 g) in pyridine (50 ml) was added to the  $\alpha^{11}$  prepared from chromium trioxide (25 g) and pyridine (10 ml). The resulting brown mixture was stirred at room temperature for 15 hr and was then diluted with ether (200 ml). The mixture was removed by filtration through Celite, and the filtrate washed with cold water (1 l.) and the organic layer separated. The aqueous layer was extracted five times with ether (total volume 1 l.), and the combined organic extracts were washed repeatedly with dilute hydrochloric acid. The dried ether solution was distilled to give an oil (22.5 g). Distillation gave 18.1 g (78.5%), bp 139° (0.55 mm). Gas chromatographic analysis on a 10-ft, F-1150 column at 220° showed the presence of the two isomers in unequal amounts (ca. 37:63). A sample collected from the rubber at 200° was analyzed.

Calcd for  $C_{14}H_{18}O_2$ : C, 77.75; H, 7.46. Found: C, 77.4; H, 7.44.

**enyl-9-oxabicyclo[4.2.1]nonane (1a) and 1-Phenyl-9-oxabicyclo[3.3.1]nonane (1b).** The above ketone mixture (18 g), 95% hydrazine (8.7 g), potassium hydroxide (35 g), and ethyl alcohol (200 ml) were heated at 130° for 1 hr. The temperature slowly raised to 175° and maintained for 2.5 hr. The mixture cooled and diluted with water (500 ml). The aqueous solution was extracted with three 150-ml portions of ether, and the combined extracts were washed with water and dried. Removal of the solvent gave 5.8 g (95%) of a colorless oil which was shown by gas chromatography on a 5-ft 5% XF-1150 column at 175° to contain 95% mixture of the [4.2.1] isomer 1a (60%) and the [3.3.1] isomer 1b (40%). Partial separation of the two isomers was achieved by distillation from pentane at –78°. Isomer 1b separated as a white solid. Recrystallization from pentane gave needles, mp –47.7°.

Calcd for  $C_{14}H_{18}O$ : C, 83.12; H, 8.97. Found: C, 83.0; H, 9.04.

The filtrate from the above fractional crystallization was enriched (75–78%) with the isomer 1a. Further fractionation was achieved by chromatography on Merck acid-washed alumina. In this fractionation, isomer 1a was obtained in about 90% isomeric purity.

**enyl-5-acetoxymethyl-9-oxabicyclo[4.2.1]nonane (6a).** To a stirred solution of mercuric acetate (32.2 g) and sodium acetate (9 g) in distilled water (200 ml) was added 1-phenyl-4-cyclooctanol (2) (20.4 g) in methanol (50 ml). The solid which precipitated after 1 hr was isolated by filtration and washed with water.

There was obtained 34 g of a mixture which contained 70% [4.2.1] isomer 6a and 30% of the [3.3.1] isomer 6b. Fractionation from benzene-pentane (1:1) gave 13.5 g of 6a, mp 140–142.5°, containing 91.5% of isomer 6a. An additional 6.5 g, mp 140–141.5°, was obtained by similar treatment of the filtrate residues. These two fractions were combined and distilled from a mixture of benzene (125 ml) and pentane (75 ml) to give 15.5 g, mp 141–143°. This material contained >95% isomer 6a.

Calcd for  $C_{14}H_{18}HgO_3$ : C, 41.69; H, 4.37. Found: C, 41.4; H, 4.15.

The distribution in the above organomercurials was determined by using 5 mg of the solid to 0.25 ml of a sodium hydroxide solution of sodium borohydride. The mixture was shaken for a few minutes and extracted with pentane. The pentane solution was analyzed by gas chromatography on an 8-ft 20% LAC-728 column at 210°.

**enyl-9-oxabicyclo[4.2.1]nonane (1a).** The mercurial 6a was suspended in 0.5 M sodium hydroxide solution (200 ml) and stirred rapidly while a solution of sodium borohydride (1 g)

in 2.5 M sodium hydroxide (30 ml) was added over 30 min. Pentane (50 ml) was added, and stirring was continued for 2 hr. The pentane layer was separated, and the aqueous layer was extracted with two 100-ml portions of pentane. The combined pentane solutions were washed with water and dried. Removal of the solvent followed by distillation gave 3.95 g (61.5%) of 1a, bp 89–92° (0.25 mm). Gas chromatographic analysis showed that the product contained less than 3% 1b.

Anal. Calcd for  $C_{14}H_{18}O$ : C, 83.12; H, 8.97. Found: C, 83.01; H, 9.05.

In a similar experiment the yield was 77%. The residue from the distillation contained mostly the fragmentation product 1-phenyl-4-cycloocten-1-ol.

**cis-4-Phenylcyclooctanol (9a).** A solution of 1a (3.0 g) in absolute ethanol (30 ml) containing 10% palladium on charcoal (0.75 g) and two drops of perchloric acid was hydrogenated at atmospheric pressure until hydrogen uptake had ceased. The catalyst was removed by filtration, and the solvent was evaporated to leave an oil which soon crystallized. Recrystallization from hexane gave 2.25 g of cis-4-phenylcyclooctanol as needles, mp 76–78.5°. An analytical sample, mp 79–80.5°, was obtained by several recrystallizations from hexane. The molecular weight obtained by mass spectrometry was 202. The infrared spectrum (KBr) showed bands at 1092, 1075, 1054, 985, 897, 759, and 703  $cm^{-1}$ .

Anal. Calcd for  $C_{14}H_{18}O$ : C, 82.30; H, 9.87. Found: C, 81.94; H, 9.92.

**cis-4-Phenylcyclooctyl Tosylate.** cis-4-Phenylcyclooctanol (5 g) was dissolved in pyridine (50 ml), and *p*-toluenesulfonyl chloride (9.3 g) was added. The solution was kept at 5° for 16 hr. Crushed ice was added to bring the total volume to 100 ml, and an oil separated. Addition of an additional 100 ml of cold water with stirring caused the oil to crystallize. The solid was collected and dissolved in methylene chloride. After drying, the solvent was removed to leave an oil which solidified on standing. There was obtained 8.6 g (98%), mp 63–65.5°. Two crystallizations from pentane gave an analytical sample, mp 67–67.5°.

Anal. Calcd for  $C_{21}H_{26}O_2S$ : C, 70.35; H, 7.31. Found: C, 70.11; H, 7.22.

**trans-4-Phenylcyclooctanol.** Crude cis-4-phenylcyclooctyl tosylate (7.45 g) was added to a solution of tetraethylammonium acetate (35 g) in reagent grade acetone (300 ml) containing Linde Molecular Sieves. The mixture was heated under reflux for 24 hr, and most of the solvent was then removed under reduced pressure. The residue was dissolved in water and extracted with ether. The ether solution was washed with water and dried. Removal of the solvent gave an oil (4.0 g). Gas chromatographic analysis on a 2-ft 20% SE 30 column at 190° showed the presence of trans-4-phenylcyclooctyl acetate (63%) and a mixture of 4- and 5-phenylcyclooctene (37%). The total reaction product was dissolved in ether (50 ml), and lithium aluminum hydride (0.5 g) was added in small portions with stirring. The mixture was heated under reflux for 1 hr and then treated cautiously with cold water and 10% hydrochloric acid. The ether layer was separated and dried. Removal of the solvent gave an oil (3.5 g). The oil was dissolved in pentane (30 ml) and was allowed to stand at –5° for 24 hr. The crystals obtained (1.7 g) had mp 60–62°. Crystallization from hexane gave 1.55 g (36.5%), mp 61–62°. An analytical sample, mp 63–64.5°, was obtained by recrystallization from hexane. The infrared spectrum (KBr) showed bands at 1049, 1035, 1010, 915, 759, and 703  $cm^{-1}$ .

Anal. Calcd for  $C_{14}H_{18}O$ : C, 82.30; H, 9.87. Found: C, 82.24; H, 9.62.

**4-Phenylcyclooctanone.** cis-4-Phenylcyclooctanol (1.0 g) in acetone (5 ml) was oxidized with an excess of Jones reagent<sup>33</sup> at room temperature for 24 hr. The mixture was poured into water and extracted with three 25-ml portions of ether. The combined extracts were washed with saturated sodium bicarbonate solution and dried. Removal of the solvent gave 0.9 g (91%) of an oil which was shown by gas chromatography on a 2-ft 20% SE 30 column at 190° to be 98% pure. A sample collected from the same column was analyzed.

Anal. Calcd for  $C_{14}H_{18}O$ : C, 83.12; H, 8.97. Found: C, 82.75; H, 8.93.

The tosylhydrazone prepared in ethanol and recrystallized from the same solvent had mp 128–130°.

Anal. Calcd for  $C_{21}H_{24}N_2O_2S$ : C, 68.07; H, 7.07; N, 7.56. Found: C, 67.65; H, 7.11; N, 7.55.

**cis-5-Phenylcyclooctanol (9b).** A solution of 1-phenyl-9-oxabicyclo[3.3.1]nonane (1b) (3.25 g) in absolute ethanol (35 ml) containing 10% palladium on charcoal (1.0 g) and six drops of perchloric acid was hydrogenated until hydrogen uptake had ceased. The catalyst was removed by filtration through Celite, and the filtrate was treated with ten drops of saturated potassium bicarbonate solution and then concentrated at reduced pressure. The residual semisolid was dissolved in ether, and the ether solution was washed with water and dried. Removal of solvent gave a white solid (3.2 g), mp 66–68°. Two crystallizations from hexane gave crystals, mp 69.5–70.5° (lit.<sup>24</sup> mp 70–71°). The infrared spectrum of the product was identical with that of *cis*-5-phenylcyclooctanol described by Cope and Kinnel.<sup>24</sup>

**Lithium Aluminum Hydride Reduction of 4-Phenylcyclooctanone.** Lithium aluminum hydride (100 mg) was added to the ketone (200 mg) in ether (5 ml). The mixture was allowed to stand at room temperature for 1 hr. Cold water and dilute hydrochloric acid were added, and the ether layer was separated, washed with water, and dried. Removal of solvent gave an oil (ca. 220 mg). This material crystallized in part from pentane at –5° after 6 weeks. The crystals obtained had mp 44–52°. The infrared spectrum showed that the product was a mixture of *cis*- and *trans*-4-phenylcyclooctanol.

Mixtures of *cis*- and *trans*-4-phenylcyclooctanol were prepared and their melting point ranges were determined (see Table I).

Table I

% <i>cis</i>	Mp, °C	% <i>cis</i>	Mp, °C
0.0	61.5–62.5	76.8	56.5–71.0

21.9	50.0–56.5	95.4	72.5–78.0
35.0	45.0–47.0	100.0	79–79.5
51.5	44.0–52.0		

**1-Phenylcyclooctanol.** The white crystalline hydrate, prepared by the method of Cope and Kinnel,<sup>24</sup> could be distilled at 125.5–127° (1.0 mm) to give the anhydrous product as a viscous oil.

*Anal.* Calcd for  $C_{14}H_{20}O$ : C, 82.30; H, 9.87. Found: C, 82.40; H, 9.83.

**Reaction of 1-Phenylcyclooctanol with Mercuric Oxide and Iodine.** Anhydrous 1-phenylcyclooctanol (25 g) was dissolved in cyclohexane (500 ml) in a 1-l. flask fitted with a stirrer and a condenser set for reflux. Calcium carbonate (50 g) and red mercuric oxide (150 g) were added, and the mixture was stirred and heated to boiling with a GE 274-w sunlamp. Iodine (100 g) was added in small portions through the condenser over a period of 45 min. The mixture was stirred and irradiated for an additional 3 hr. After cooling, the solids were removed by filtration, and the filtrate was washed with 10% sodium thiosulfate solution (350 ml) and

dried. Removal of solvent gave a yellow oil (35 g). The oil was dissolved in pentane and chromatographed on acid-washed alumina (350 g). Elution with pentane (1200 ml) gave an oil (11.7 g) in several fractions. Distillation afforded 7.25 g (29.3%) of a mixture of 1a and b, bp 101–115° (0.75 mm). Gas chromatographic analysis indicated that the two ethers were present in about equal amounts. The mixture was dissolved in pentane (65 ml), and the solution was cooled at –75° for 30 min. The crystals were isolated to give 2.1 g of 1b uncontaminated with 1a. The filtrate yielded an oil containing 1a (65%) and 1b (35%). The yield of the ether mixture varied from 20 to 35% in similar runs.

Further elution of the column during the chromatography yielded a third product which was shown to be 8-iodo-1-phenyloctan-1-one (8). After several recrystallizations from pentane it had a melting point of 41.5–42°.

*Anal.* Calcd for  $C_{14}H_{19}IO$ : C, 50.92; H, 5.79; I, 38.43. Found: C, 51.21; H, 5.79; I, 38.18.

**Reduction of 8-Iodo-1-phenyloctan-1-one (8).** The iodide (0.5 g) was dissolved in glacial acetic acid (7 ml), and zinc dust (1.0 g) was added. The mixture was heated on a steam bath with occasional stirring for 20 min. The solution was decanted, and the residual solid was washed several times with pentane. Water was added to the acetic acid-pentane mixture, and the organic layer was separated. The pentane solution was washed several times with saturated sodium bicarbonate solution and dried. Removal of the solvent gave an oil (300 mg) which was 90% pure by gas chromatography. The infrared spectrum of a sample collected from a 2-ft 20% SE 30 column at 200° was identical with that of heptyl phenyl ketone described below.

A portion was converted to the dinitrophenylhydrazone which had mp 113–115° after recrystallization.

**Heptyl Phenyl Ketone.** Octanoic acid (5.0 g) and thionyl chloride (7 ml) were heated on a steam bath for 1 hr. The excess thionyl chloride was removed at reduced pressure, and the residue was dissolved in benzene (10 ml). The benzene solution was added slowly (caution) to a suspension of aluminum chloride (10.0 g) in benzene (50 ml). When the addition was complete, the mixture was heated on a steam bath for 1 hr and then was poured onto crushed ice. The benzene layer was separated, washed with 10% sodium bicarbonate solution and water, and dried. Removal of the solvent left an oil which was purified by dissolution in pentane and addition of activated charcoal. The pentane solution was filtered and cooled to –10°. The crystals which could be obtained by rapid filtration melted at room temperature. A pure sample of heptyl phenyl ketone (a band appeared in the infrared at  $1685\text{ cm}^{-1}$ ) was obtained by preparative gas chromatography on a 2-ft 10% SE 30 column at 200°.

The 2,4-dinitrophenylhydrazone had mp 113–116° after recrystallization from ethanol. It showed no melting point depression when mixed with the 2,4-dinitrophenylhydrazone of heptyl phenyl ketone prepared by reduction of the iodide described above.

Received January 16, 1967

**Abstract:** A previous study on the reactivity of isopropyl methylphosphonofluoridate with various anions of hydroxybenzenes indicated that the incorporation of a cationic site into the benzene nucleus increased the reactivity of the anion relative to its basic strength. In this work, the reactivities of different cationically substituted nucleophiles have been determined. One class of nucleophiles, called " $\alpha$ " nucleophiles because they possess an unshared electron pair on the ( $\alpha$ ) atom adjacent to the attacking atom, showed no (anions of hydroxamic acids) or only a slight (anions of keto oximes) "charge" effect, *i.e.*, their reactivities were equal to or only slightly greater than would be expected for a nucleophile of the same class of the same basic strength but possessing no cationic group in the molecule. A second class of nucleophiles, the anions of hydrated aldehydes, similar to the hydroxybenzenes in that the atom adjacent to the attacking atom contained no unshared electron pair, exhibited a "charge" effect qualitatively and quantitatively similar to that shown by the hydroxybenzenes. An explanation for the different responses to the "charge" effect shown by the " $\alpha$ " and "non- $\alpha$ " nucleophiles is offered. The "charge" effect studies are not only useful practically, but also may be used in separation of factors in nucleophilicity. These studies support the designation of a separate classification for " $\alpha$ " nucleophiles when discussing reactivity.

recent studies<sup>2</sup> it has been observed that anions of hydroxybenzenes containing cationic groups are more reactive than other hydroxybenzenes of the same protonicity in displacement of fluoride ion from isopropyl methylphosphonofluoridate (GB) in aqueous solution. It was also shown that the magnitude of the increase in reactivity was related to (a) the distance between the cationic and anionic sites, the difference increasing as the distance between the loci of the charges decreases, (b) to the number of cationic groups in the nucleophile, each cationic site contributing independently in accordance with its distance from the anionic site. For example, it was shown that the monoanion of protonated 3-aminomethylcatechol was approximately five times as reactive as the monoanion of a catechol of the same proton basicity but possessing no cationic group, whereas the monoanion of 4-aminomethylcatechol was less than twice as reactive as a cationic monocatecholate anion of comparable basicity. Also, the monoanion of the protonated 3-ethylaminomethylcatechol was approximately six times as reactive as the monoanion of the diprotonated, 3,6-bis(dimethylaminomethyl)catechol 38, and the monoanion of the 6-tris(dimethylaminomethyl)catechol 75 times as reactive as their noncationic-bearing, but same protonicity, analogs.<sup>2b</sup> The enhanced reactivity shown by a nucleophile containing a cationic site ("charge" effect) has been explained on the basis that  $pK_a$  of the conjugate acid is a true measure of the basicity of the nucleophile toward neutral substrates; that the basicity of a cation-bearing nucleophile is greater than a neutral substrate than would be predicted from the  $pK_a$  of the conjugate acid, since the Coulomb repulsion factors operative in ionization phenomena are absent in reaction with a neutral substrate.

While the effect of a cationic group on the reactivity of the hydroxybenzenes in displacement reactions of the phosphonyl ester, GB, has been established, the effect of cationic substitution in nucleophiles other than the hydroxybenzenes in this displacement reaction has not been assessed. In this paper, we report on the effect of cationic substituents on the reactivity of the anions of hydroxamic acids, keto oximes, and hydrated aldehydes in displacement of fluoride ion from GB in aqueous solution.<sup>3</sup>

## Experimental Section

**Materials.** Picoline, isonicotinic, nicotinehydroxamic acids, and the corresponding methiodides were synthesized according to the directions of Hackley, *et al.*<sup>4</sup> *o*-Diethylaminoethoxybenzohydroxamic acid was kindly supplied by Dr. R. E. Plapinger. Chloral, pyruvic aldehyde (as an aqueous solution), and 2-, 3-, and 4-pyridine carboxaldehydes were obtained from commercial sources. The 2- and the 4-pyridine carboxaldehydes were converted to their methiodides according to the procedure of Steinberg, Poziomek, and Hackley.<sup>5</sup> The methiodide of 1,1-dimethyl-2-dimethylamino-propionaldehyde was prepared from the commercially available free base by reaction with methyl iodide in diethyl ether, mp 230°. *Anal.* Calcd for  $C_8H_{18}INO$ : C, 35.4; H, 6.6. Found: C, 35.5; H, 6.8. Compounds 1, 2, 3, and 11 in Table III were kindly supplied by Dr. G. M. Steinberg.<sup>6</sup> The other compounds were prepared according to published procedures.<sup>4</sup> All compounds were of high purity using elemental analyses, neutralization equivalents, and sharpness of melting point criteria except pyruvic aldehyde which was determined to be 49.6% by analysis.

**Determination of  $pK_a$  Values.** The compounds were made up to be approximately 0.01 *M* with the ionic strength adjusted to 0.1 with KCl. A 3-ml aliquot, adjusted to the desired temperature and maintained at that temperature to  $\pm 0.1^\circ$ , was titrated potentiometrically with a microsyringe (total volume 0.5 ml) cali-

brated in units of 0.005 ml, and estimable to 0.0005 ml with 0.1 *N* CO<sub>2</sub>-free NaOH solution. (A Radiometer automatic titrator was used.)

**Determination of Reaction Velocities and Rate Constants.** The general procedure for determination of reaction velocities and methods for calculation of the bimolecular rate constants has been previously described.<sup>2a,7</sup>

In all cases the nucleophiles were in sufficient excess so that their concentrations remained, to all intents and purposes, constant, resulting in first-order kinetics.

For the hydroxamic acids and the hydrated aldehydes, the reaction velocities were determined by analyzing the GB concentrations with time, enzymatically, taking advantage of the anticholinesterase properties of GB.

The reaction velocities for the  $\alpha$ -keto oximes were determined manometrically from the CO<sub>2</sub> produced upon reaction of the acidic products of GB oxime reaction with sodium bicarbonate. The half-time of the reaction was taken as the time required to produce 50% of the total CO<sub>2</sub> produced. The bimolecular rate constants were calculated from the first-order rate constants and the concentration of the anions according to the equation

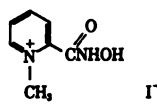

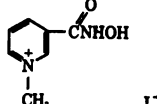

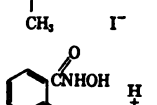

$$k_2 = k_{\text{obsd}}([H^+] + K_a)/K_a[C_0]$$

where  $k_2$  is the bimolecular rate constant in l. mole<sup>-1</sup> min<sup>-1</sup>,  $k_{\text{obsd}}$  is the first-order rate constant in min<sup>-1</sup>,  $K_a$  is the ionization constant of the hydroxamic acid, oxime, or hydrated aldehyde, and  $[C_0]$  is the initial concentration of the acid.

## Results

Table I gives the  $pK_a$  values of four cationic-bearing hydroxamic acids and the bimolecular rate constants of their anions with GB. Table II contains the data by which one can compare the reactivities of the anions of the above hydroxamic acids with the anions of noncationic-bearing hydroxamic acids. The values listed under the heading "Log  $k_c$ " have been calculated from the equation<sup>8,9</sup> relating the log of the bimolecular rate

	5.95	0.89	0.91	+0.02
	8.42	2.87	2.80	-0.07

<sup>a</sup> Calculated from the equation  $\log k_2 = 0.80pK_a - 3.87$  at 30° (see Table I).

constant with the  $pK_a$  for the nucleophile, *viz.*,  $\log k_c = 0.80pK_a - 3.87$ ; those under the heading "Log  $k_2$ " are the experimentally determined values. Log  $k_2/k_c$  then, denotes the deviation of the experimental value from that predicted from the equation of the "normal" nucleophiles of the class under study.

The almost negligible (within experimental error) difference between the logarithms (<0.1, see ref 2a) of bimolecular rate constants of the cationic hydroxamic acids ( $k_2$ ) and the hydroxamic acids containing no cationic groups ( $k_c$ ), considering that the distance of separation between the cationic and anionic sites and the type of group producing the charge (*i.e.*, pyridine, aliphatic amine) has been varied over rather wide limits, is strong evidence that there is no "charge" effect on the hydroxamic acid anion similar to that found for the hydroxybenzenes.

The data (Table III) were used to determine the effect of "charge" on the nucleophilicity of the anions of keto oximes.

A plot of the data in Table III is shown in Figure 1, the circles representing values of noncationic-bearing oximes, whereas the x's are for compounds containing a positive charge. The equation of the line drawn through the circular points ("base" line) is

$$\log k_c = 0.642pK_a - 3.25$$

Table IV lists the relevant data for assessing the "charge" effect. As in the previous instance, the values listed under the heading "Log  $k_c$ " have been calculated from the equation of the "base" line relating the bimolecular rate constant of the anion of keto oximes with GB and the  $pK_a$  of the keto oximes, *viz.*,  $\log k_c = 0.642pK_a - 3.25$ . Again,  $\log k_2/k_c$  is the deviation of the experimental value from that predicted from the equation of the "normal" keto oximes. These data suggest that there is an effect of charge on the reactivity of the anions of keto oximes although, perhaps, not as pronounced as in the case of the hydroxybenzenes. A similar conclusion can be drawn from

an analysis of the data of Green, *et al.*,<sup>10</sup> on the rate constants of oximes with GB.

Data on seven aldehydes, three of which contain cationic groups, and ninhydrin are shown in Table V. That the effect of a cationic substituent in a hydrated aldehyde on the nucleophilicity of its anion is marked can be seen by comparison of the reactivities of the anions of chloral and 2-formyl-1-methylpyridinium iodide, and pyruvic aldehyde and 4-formyl-1-methylpyridinium iodide. The  $\text{pK}_a$  values of the first two compounds are almost identical, *viz.*, 9.94 and 9.95, yet their reactivities differ by almost an order of magnitude [ $k_2(\text{chloral}) = 32$  l. mole<sup>-1</sup> min<sup>-1</sup>;  $k_2(2\text{-formyl-1-methylpyridinium iodide}) = 215$  l. mole<sup>-1</sup> min<sup>-1</sup>]. Similarly, the bimolecular rate constant for the reaction between GB and the anion of pyruvic aldehyde ( $\text{pK}_a$  of conjugate acid = 11.0) is 102 l. mole<sup>-1</sup> min<sup>-1</sup>; the bimolecular rate constant for the reaction between GB and the anion of 4-formyl-1-methylpyridinium iodide, whose conjugate acid  $\text{pK}_a$  is less than that of pyruvic aldehyde, *viz.*, 10.72, and hence may be expected to be less than 102 l. mole<sup>-1</sup> min<sup>-1</sup>, is 302 l. mole<sup>-1</sup> min<sup>-1</sup>.

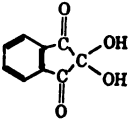

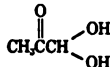

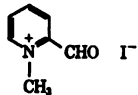

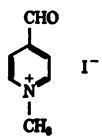

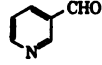

Moreover, the effect of charge appears to be quantitatively similar in the hydrated aldehydes and the hydroxybenzenes. It was shown in the latter series that  $\log k_2/k_c$  (where  $k_2$  is the bimolecular rate constant of the anion of "charged" hydroxybenzene with GB and  $k_c$  is the bimolecular rate constant of an anion of hydroxybenzene of the same proton basicity but possessing no cationic group) could be estimated from the relationship

$$\log k_2/k_c = c/d^2$$

where  $c$ , a proportionality constant, equals 12.7 and  $d$  is the distance between the cationic and anionic sites in Angstrom units. The distance between the cationic and anionic sites in the anion of 2-formyl-1-methylpyridinium iodide is estimated from Dreiding models to be 2.64 or 3.64 Å depending upon whether the anionic site is assumed to reside on the oxygen atom

(10) A. L. Green, G. L. Sainsbury, B. Saville, and M. Stanfield, *J. Chem. Soc.*, 1583 (1958).

**Table V.** Summary of Data for Reaction of Hydrated Aldehydes and Ninhydrin with GB at 25°

Compd	p <i>K</i> <sub>a</sub>	<i>k</i> <sub>2</sub> , l. mole <sup>-1</sup> min <sup>-1</sup>
	8.82	13.3 ± 0.1 <sup>a</sup>
	9.95	32.0 ± 0.4 <sup>a</sup>
	11.0	102 ± 5 <sup>b</sup>
	9.94	214 ± 2.5 <sup>a,d</sup>
	10.72	302 ± 6 <sup>a,d</sup>
	13.6	8450 ± 350 <sup>a</sup>
	13.0	960 ± 112 <sup>a</sup>
	12.05	459 ± 37 <sup>c</sup>

<sup>a</sup> Two determinations. <sup>b</sup> Three determinations. <sup>c</sup> Five determinations. <sup>d</sup> Data obtained with the cooperation of Dr. George M. Steinberg.

closest to or farthest from the nitrogen atom. If the latter value is chosen, then, from data on the hydroxybenzenes, it would be predicted that the reactivity of 2-formyl-1-methylpyridinium iodide with GB would be 12.7/3.642<sup>2</sup> or 0.96 log unit higher than that of chloral (hydrated aldehyde of the same p*K*<sub>a</sub> but possessing no cationic group). The actual difference is 0.83 log unit.

Also, the bimolecular rate constant of the reaction between GB and the anion of a hydrated aldehyde (containing no cationic substituent) whose conjugate acid has a p*K*<sub>a</sub> equal to 10.72 may be expected to be<sup>11</sup> approximately 87 l. mole<sup>-1</sup> min<sup>-1</sup>. Hence the enhancement in rate shown by the 4-formylpyridinium methiodide over that which might be expected from its p*K*<sub>a</sub> is 0.54 log unit (log 302 - log 87). The distance between the anionic and cationic sites in the 4-formylpyridinium methiodide from Dreiding models is 4.88 Å. Using this value for *d*, and *c* = 12.7, one would predict from the data on hydroxybenzenes a logarithmic increase in rate of 0.53 log unit, in very good agreement with the value of 0.54 obtained above.

Although of doubtful quantitative significance because of the high probability of error in extrapolation of the

(11) The least-squares equation of the line using the data for chloral, pyruvic aldehyde, 3- and 4-formylpyridine, and ninhydrin is: log *k*<sub>2</sub> = 0.465p*K*<sub>a</sub> - 2.95. The bimolecular rate constant for the reaction between a noncationically substituted hydrated aldehyde of p*K*<sub>a</sub> = 10.22 would be expected to be ca. 87 l. mole<sup>-1</sup> min<sup>-1</sup>.

data to pH 13.6, it is nevertheless of qualitative value that the anion of a hydrated aldehyde containing no cationic group whose conjugate acid has a p*K*<sub>a</sub> of 13.6 may be expected to have a *k*<sub>2</sub> value of ca. 1800 l. mole<sup>-1</sup> min<sup>-1</sup>. The value found for the cation-bearing anion of the aldehyde, 2,2-dimethyl-3-trimethylammonio-propanol iodide (p*K*<sub>a</sub> of the conjugate acid = 13.6), was considerably higher, viz., 8450 l. mole<sup>-1</sup> min<sup>-1</sup>.

Table VI lists the distances of separation between the cationic and anionic sites in anions of hydroxamic acids, keto oximes, and hydrated aldehydes, the expected deviations from "normal" that these nucleophiles would show if their behavior were similar to that of the hydroxybenzenes, and the deviation calculated as the logarithm of ratio of the experimentally determined bimolecular rate constants with GB to the bimolecular rate constants of a nucleophile in the same class and of the same proton basicity.

The values of *d* shown in Table VI for the keto oximes require explanation. The distance of separation of the charges in the keto oximes and hydroxamic acids is difficult to estimate due to free rotation of groups; Dreiding models indicate that the distance of separation of charge in the keto oximes designated as compounds 2 and 3 in Table III can vary from 2.8 to 4.4 Å. However, with the larger value there is no steric crowding of the oximino group by the alkyl groups on the amine. That there should be no steric obstruction is suggested by the almost identical deviations from the "base" line shown by compounds 2 and 3 in Figure 1, even though the groups attached to the nitrogen are different. The model having a distance of separation of ca. 4 Å was one in which substitution of ethyl groups for a hydrogen and a methyl (conversion of compound 2 to compound 1 in Table III) produced a structure in which the oxygen of the oximino group was slightly sterically hindered. Steric hindrance in compound 1 is suggested by kinetic data (see Figure 1 and ref 2a). Similar considerations led to a value of ca. 5 Å for the distance of charge separation in compound 11.

In all cases the locus of positive charge was assumed to reside on the pyridinium or amino nitrogens; the site of high electron density was assumed to be on the oximino oxygens in the case of the anions of the hydroxamic acids<sup>12</sup> and keto oximes and on the alcoholic oxygen in the case of the hydrated aldehydes.

## Discussion

From the data in Tables II, IV, V, and VI, one concludes that a cationic substituent greatly enhances the reactivity of anions of hydrated aldehydes (relative to their proton basicities), enhances only slightly the reactivity of the keto oximate anion, and has negligible effect upon the reactivity of anions of the hydroxamic acids. Furthermore, the response of the hydrated

(12) The choice of the locus of high electron density is obviously arbitrary; in the anions of the hydroxamic acids and keto oximes, the sites of high electron density can be assumed to reside on either of two oxygens or the oximino nitrogen. O. Exner and B. Kakac [Collection Czech. Chem. Commun., 28, 1965 (1963)] conclude from ultraviolet absorption studies on hydroxamic acids and their anions that the site of electron density in the anion is on the carbonyl oxygen; G. M. Steinberg and R. W. Swidler, *J. Org. Chem.*, 30, 2362 (1965), and R. E. Plapinger, *ibid.*, 24, 802 (1959), argue that the anion exists in at least two and possibly three forms.

<sup>a</sup> Calculated from the fraction  $c/d^2$ , where  $c = 12.7$ ,  $d$  = distance of separation of charges in Angstrom units. <sup>b</sup>  $k_2$  = experimental bimolecular rate constant of the reaction between GB and the anion of compound listed;  $k_0$  is the bimolecular rate constant calculated from the following equations: hydroxamic acids:  $\log k_0 = 0.80pK_a - 3.87$ ; keto oximes:  $\log k_0 = 0.642pK_a - 3.25$ ; hydrated aldehydes:  $\log k_0 = 0.456pK_a - 2.95$ , where  $pK_a$  is the negative logarithm of the acid dissociation constant of the compound listed. The equations relating  $\log k_2$  with  $pK_a$  are from ref 3 (hydroxamic acids), Figure 1 of this paper (keto oximes), and Table V of this paper (data on the reactivity of the anions of chloral, pyruvic aldehyde, 3- and 4-formylpyridine, and ninhydrin with GB). <sup>c</sup> This distance can vary from approximately 2.8 to 4.4 Å, depending upon the configuration adopted, a "stretched out" configuration giving a value of 4.4. <sup>d</sup> "Stretched out" configuration. <sup>e</sup> The positive charge is assumed to reside on the nitrogen; the negative, on the oxygen. The value of superscript  $f$  is the smallest distance of separation; that of  $e$ , the largest.

aldehydes to the "charge" effect is quantitatively similar to that of the hydroxybenzenes.

The reactivity of the anions of compounds with GB increases in the order: hydrated aldehydes ~ phenols < oximes < hydroxamic acids whereas the effect of introduction of a charged substituent decreases in the same order. One is tempted to relate the "charge" effect with reactivity, the "charge" effect becoming less important as the intrinsic reactivity of the nucleophile increases. However, the anions of hydroxybenzenes of the catechol and pyrogallol type respond to the "charge" effect equally as well as the anions of phenol or of the hydrated aldehydes do, and yet have re-

activities of the same order as those of the anions of the oximes and hydroxamic acid.<sup>13</sup> Correlation of "charge" effect with the reactivity is not justified. Nor does there appear to be any correlation between the magnitude of the effect caused by introduction of a cationic substituent and the value of the slope (a measure of the degree of bond formation in the transition state) in the equation relating the logarithm of the bimolecular rate constant with the  $pK_a$  of the

(13) Compare, for example, the equation of the line relating the bimolecular rate constants of the anions of pyrocatechols with GB, viz.,  $\log k_2 = 0.76pK_a - 3.70$ , with that of the anions of hydroxamic acids and GB, viz.,  $\log k_2 = 0.80pK_a - 3.87$ .

conjugate acid of the reacting nucleophile for different classes of nucleophiles. The slopes for the anions of phenols,<sup>2a</sup> catechols, and pyrogallols<sup>2b</sup> (which show marked "charge" effects) are 0.59, 0.80, and 0.76; those of keto oximes and hydroxamic acids are 0.64 and 0.80.

It is, however, perhaps of some significance that of the classes of nucleophiles studied, those which appear to respond only slightly (keto oximate anion) or not at all (anions of hydroxamic acids) to the "charge" effect are " $\alpha$ " nucleophiles,<sup>14</sup> that is, the atom adjacent to the nucleophilic one contains an unshared pair of electrons, whereas those which show marked "charge" effects (anions of hydrated aldehydes, hydroxybenzenes) are "non- $\alpha$ " nucleophiles.<sup>15</sup>

Because the anions of the keto oximates are partially affected by a cationic substituent, they may be classified as " $\alpha$ " nucleophiles possessing some "non- $\alpha$ " character. In fact, if one assumes that the keto oximate anion possesses 68% " $\alpha$ " character and 32% "non- $\alpha$ " character (the rationale for the assignment of 68 and 32% is given below) and that the "charge" effect acts only on "non- $\alpha$ " nucleophiles, then it can be shown that the predicted  $\log k_2/k_c$  for compounds 2 and 3 (distance of separation of charged groups is approximately 4 Å) is 0.25 and for compound 11 (distance of separation is approximately 5 Å), 0.16, in good agreement with the values of  $\log k_2/k_c$ , viz., 0.19, 0.21, and 0.13, found for the three compounds (Table VI).

The values of 68 and 32% were arrived at by treating the free energy of activation as a sum of independent contributions<sup>16</sup> attributable to the " $\alpha$ " and "non- $\alpha$ " characters of the nucleophile. Thus, one may write

$$\log k_2 = \log k_\alpha + \alpha_n \log k_{\alpha n} \quad (1)$$

where  $k_2$  is the bimolecular rate constant for the nucleophile in question with a given substrate at a given temperature;  $k_\alpha$  and  $k_{\alpha n}$  are the bimolecular rate constants due to " $\alpha$ " and "non- $\alpha$ " contributions for a given basicity of the nucleophile; and  $\alpha$  and  $\alpha_n$  are constants ranging from 0 to 1 with  $\alpha + \alpha_n = 1$ .

For reactions with GB, it can be assumed that values of  $k_\alpha$  and  $k_{\alpha n}$  can be obtained from data on the reactivity of the anions of hydroxamic acids (pure " $\alpha$ ") and phenols (pure "non- $\alpha$ "). If the nucleophile in question is the keto oximate anion, the  $\log k_2$  can be calculated from the equation

$$\log k_2 = 0.642pK_a - 3.25$$

Thus for a keto oximate anion whose conjugate acid has a  $pK_a = 7.5$ ,<sup>17</sup>  $\log k_2 = 1.57$ ;  $\log k_\alpha = 2.13$  (calcu-

lated from the equation relating the bimolecular rate constants of the reaction between GB and hydroxamic acid anions, viz.,  $\log k_\alpha = 0.80pK_a - 3.87$ , where  $pK_a = 7.5$ ); and  $\log k_{\alpha n} = 0.390$  (calculated from the equation relating the bimolecular rate constants of the reaction between GB and phenolate anions at 25°, viz.,  $\log k_{\alpha n} = 0.598pK_a - 4.172$ , and correcting to 30° using an Arrhenius activation energy value of 12.0 kcal/mole<sup>18</sup>).

Substituting the values for  $\log k_2$ ,  $\log k_\alpha$ , and  $\log k_{\alpha n}$  into eq 1 gives  $\alpha_n$  equal to 0.32. Thus, by this line of reasoning the keto oximate anion possesses 68% " $\alpha$ " character and 32% "non- $\alpha$ " character.

Although other factors are doubtless of importance in nucleophilic reactivity, the success in quantitatively predicting the effect of charge in the keto oximates lends support to the treatment given herein and to the conclusion that the "charge" effect is applicable only to "non- $\alpha$ " nucleophiles. Also, the "charge" effect is useful in distinguishing between two effects, both related to proton basicity, in displacement of fluoride ion from GB. The lack of response of the " $\alpha$ " nucleophiles to the "charge" effect is considered evidence for (as Edwards and Pearson suggest<sup>14</sup>) an independent source in nucleophilicity.

Although one can state that there is a difference in the effectiveness of a cationic group on the reactivity of " $\alpha$ " and "non- $\alpha$ " nucleophiles, the reason for the difference is not immediately apparent. One can speculate that since the reactivity of an anion of a charged hydroxamic acid to a neutral substrate is reflected in the  $pK_a$  of its conjugate acid, whereas the reactivities of "non- $\alpha$ " nucleophiles are not, that the processes affecting ionization in the conjugate acids of the two nucleophiles are different. It has recently been suggested, for example, that the so-called "inductive" effect in the base-weakening effects of the trimethylammonio group on aniline may be a field effect.<sup>19</sup> The fact that *m*-aminophenyltrimethylammonium chloride is a weaker base than the *para* isomer is cited as evidence<sup>20</sup> that the trimethylammonio group does not exert a  $\pi$ -inductive effect. Likewise, in the phenol series, *m*-trimethylammoniumphenol is a stronger acid than the corresponding *para* isomer, suggesting that in the phenols also, the trimethylammonio group does not exert its effect *via*  $\pi$  induction. In contrast, the methiodide of isonicotinehydroxamic acid is a stronger acid than the methiodide of nicotinehydroxamic acid (Table I). It is therefore reasonable to postulate that the trimethylammonio group exerts a field effect in the phenols and a " $\pi$ -inductive" effect in the hydroxamic acids.

Thus the trimethylammonio group will act as an electron sink in the hydroxamic acids; that is, there will be no electrostatic contribution by repulsion of the dissociating proton in the ionization of " $\alpha$ " acids. The cationic group, therefore, is no different in its action from any other electron-withdrawing group,

effects in the keto oximes on compounds having  $pK_a$  values between 7 and 8.5 (Table IV).

(18) The Arrhenius activation energies for the reaction between GB and the anions of *m*-nitrophenol, *p*-nitrophenol, and *m*-hydroxybenzaldehyde are 11.3, 12.0, and 12.6, respectively (J. Epstein, Ph.D. Thesis, University of Delaware, 1966).

(19) M. J. S. Dewar and P. J. Grisdale, *J. Am. Chem. Soc.*, **84**, 3548 (1962).

(20) J. D. Roberts, R. A. Clement, and J. J. Drysdale, *ibid.*, **73**, 2181 (1951).

(14) J. O. Edwards and R. G. Pearson, *J. Am. Chem. Soc.*, **84**, 16 (1962).

(15) Conceivably, the hydroxybenzenes may be considered to be partial " $\alpha$ " nucleophiles inasmuch as the  $\alpha$  atom is conjugated with the  $\beta$  atom and hence partially "owns" an unpaired set of electrons. However, the hydroxybenzenes are classed as "non- $\alpha$ " nucleophiles because of the similarities in the nucleophilicities of their anions and the anions of alcohol and the hydrated aldehydes, whose classification as "non- $\alpha$ " nucleophiles is unequivocal. For example, Bruice, *et al.*, *Biochemistry*, **1**, 7 (1962), found in displacement of *p*-nitrophenol from *p*-nitrophenylacetate that phenols and aliphatic alcohols fall on the same line in a Brønsted plot; in displacement of fluoride ion from GB, anions of phenols and hydrated aldehydes of similar basicity have equal reactivities (cf. phenol  $pK_a = 9.78$ ,  $k_2 = 34$  l. mole<sup>-1</sup> min<sup>-1</sup>; with chloral,  $pK_a = 9.95$ ,  $k_2 = 32$  l. mole<sup>-1</sup> min<sup>-1</sup> (Table V)).

(16) For other examples of such treatment see R. W. Taft, Jr., in "Steric Effects in Organic Chemistry," M. S. Newman, Ed., John Wiley and Sons, Inc., New York, N. Y., 1965.

(17) An anion, whose conjugate acid has a  $pK_a = 7.5$ , has been selected since these calculations will be used to determine "charge"

e.g., NO<sub>2</sub>, CN, etc. In the case of the acids of the nucleophiles of the phenol type, on the other hand, a substantial contribution to the ionization constant is made by electrostatic interaction of the cationic site and the proton, a repulsion of the latter assisting in its removal by the water molecules. Hence the basicity of the "α" nucleophile possessing a cationic charge to a neutral species will be reflected in its basicity to a proton (pK<sub>a</sub>) and the reactivity of a "charged α" nucleophile is predictable from its pK<sub>a</sub>.

Finally, it appears desirable to point out the implications of these conclusions on the general factors affecting nucleophilicity<sup>14,21,22</sup> and especially on the high reactivity shown by "α" nucleophiles.<sup>14</sup> In the anions of phenols and hydrated aldehydes, it is thought that the site of high electron density is highly localized in the nucleophile's oxygen,<sup>23</sup> whereas in the "α"

nucleophiles, it is felt that the electrons are highly mobile and distributed over several of the electronegative atoms.<sup>24</sup> The lack of mobility of the highly localized electrons is responsible for the relatively low slope (β) values<sup>21</sup> in the correlation equations of rate and pK<sub>a</sub> of the "non-α" nucleophiles in their reactions with organophosphorus esters. (Higher slopes are obtained with such nucleophiles if other factors, such as H bonding, contribute to the formation of the transition state, e.g., in catechol.) In contrast, the highly mobile electrons in the "α" nucleophile are much more available for transition-state bond formation and show generally higher slopes. It is interesting, too, in this connection that β for the anions of keto oximes, which it is postulated contain some "non-α" character, lies between that of the anions of phenols and those of hydroxamic acids.

(22) J. F. Bunnett, *Ann. Rev. Phys. Chem.*, 14, 271 (1963).

(23) In apparent contradiction to the postulation that the electron density is localized on the phenolic oxygen, it is well known that phenols react with many electrophiles at ring positions rather than at the phenolate oxygen, indicating that there is a high electron density at the ring

positions. It is our feeling, however, that the high ring electron density results from the approach of the electron-deficient reactant; that in the presence of a localized substrate the distribution of electrons in the phenolate anions will be localized on the phenolic oxygen.

## Secondary Deuterium Isotope Effects on a Cyclic Allylic Rearrangement<sup>1</sup>

Kirk D. McMichael

*Contribution from the Department of Chemistry, Washington State University, Pullman, Washington 99163. Received November 12, 1966*

**Abstract:** Secondary α- and γ-deuterium isotope effects on the cyclic intramolecular rearrangement of allyl thionbenzoate to allyl thiolbenzoate have been measured. The α effect (1.06) is significantly smaller than that observed for (1.10–1.12) carbonium ion, carbanion, or radical pathways. With the γ effect (0.97), this result indicates that these effects are useful mechanistic criteria for allylic rearrangements. These results also indicate that the transition state structurally resembles reactant more than product, suggesting that this type of study will be useful in characterizing the position of a transition state along a reactant–product coordinate in such reactions.

Intramolecular allylic rearrangement reactions have occupied a position of considerable importance in the development of organic reaction mechanism theory.<sup>2</sup> Many of these reactions have been important in the study of carbonium ion processes<sup>3</sup> and others have been resistant enough to ordinary mechanistic probes to earn the sobriquet "no mechanism" reactions.<sup>4</sup>

It has long been recognized that a continuum of merging carbonium ion pair and cyclic mechanisms may connect these two classes of allylic rearrangements.<sup>5</sup> Since examples of carbanion and homolytic intramolecular allylic rearrangements are now known,<sup>2,6</sup> this

mechanistic continuum may be generalized to include, at the noncyclic limit, reactions of all three charge types, carbonium ion, radical, and carbanion, each merging with a cyclic reaction scheme at the other end of the continuum.

No satisfactory method for characterizing the mechanism of an intramolecular allylic rearrangement in terms of such a general cyclic to noncyclic continuum is presently available. A mechanistic criterion suited to this purpose should be insensitive to medium effects to permit its use in a wide variety of environments including the gaseous state. Methods for qualitatively placing a particular reaction along a carbonium ion cyclic continuum have been developed<sup>7</sup> and depend primarily on estimation of the polarity of the kinetically important transition state by means of kinetic solvent or substituent effects; reactions which are sensitive to polar effects are considered to involve carbonium ion pair mechanisms, and those which are insensitive are assigned cyclic mechanisms. The interpretation of

these effects rests on a large body of empirical evidence concerning the magnitudes of polar solvent and substituent effects on carbonium ion reaction rates;<sup>8</sup> these methods are not directly applicable to the merging carbanion cyclic or homolytic cyclic continua.

The fundamental difference between mechanisms for cyclic and noncyclic reactions is one of timing. In an extreme noncyclic reaction mechanism, the bond between the migrating group and carbon atom to which it was originally attached ( $\alpha$ -carbon) is essentially completely broken before the onset of bonding between the migrating group and the migration terminus ( $\gamma$ -carbon), as indicated in eq 1. In contrast, the transition state

for a cyclic reaction is characterized by significant bonding between the  $\gamma$ -carbon and the migrating group *before* completion of bond breaking between the  $\alpha$ -carbon and the migrating group (eq 2). Thus a cri-

terion capable of distinguishing between synchronous and stepwise bond-breaking and bond-making processes should be capable of distinguishing between cyclic and noncyclic mechanisms, or, more subtly, of placing a reaction on a general continuum between these extremes.

Recent investigations have shown that the study of secondary  $\alpha$ -deuterium isotope effects ("effects of the first kind," in Halevi's terminology<sup>9</sup>) are valuable probes in studying the timing of bond-making and bond-breaking processes.<sup>10</sup> For our purposes, such effects have several valuable characteristics. First, Seltzer<sup>11</sup> has pointed out that the magnitude of the rate retardation associated with the substitution of one deuterium atom for a hydrogen atom  $\alpha$  to the leaving group is remarkably constant at 10–12%, regardless of the charge type (carbanion, free radical, or carbonium ion) of the reaction. Second, inverse isotope effects have been observed upon substitution of deuterium for hydrogen at doubly bonded carbon atoms for a variety of reactions in which these carbons undergo a trigonal to tetrahedral conversion, similar to that envisioned for the  $\gamma$ -carbon in a cyclic allylic rearrangement transition state.<sup>9</sup> Third, since secondary deuterium isotope effects are basically substituent effects and appear to be unaffected by reaction medium effects, their use as mechanistic criteria in studying allylic rearrangement reactions should be restricted only by the availability of kinetic or other means of measuring the deuterium isotope effect with adequate precision and the ability to introduce deuterium atoms at the  $\alpha$ - and  $\gamma$ -carbons of the appropriate allylic system.

(10) S. Seltzer and F. T. Dunne, *J. Am. Chem. Soc.*, **87**, 2628 (1965); S. Seltzer, *ibid.*, **87**, 1534 (1965).

(11) S. Seltzer, *ibid.*, **83**, 2625 (1961).

In this framework, cyclic allylic rearrangement transition states should exhibit smaller than normal rate retardations due to  $\alpha$ -deuterium substitution and significant rate accelerations due to  $\gamma$ -deuterium substitution, in keeping with the synchronous nature of bond-making and bond-breaking processes. In contrast, noncyclic rearrangements should exhibit normal  $\alpha$ -deuterium isotope effects, since bond breaking at the transition state should be about as complete in their reactions as it is in the examples of carbonium ion, carbanion, and radical reactions for which deuterium isotope effects have been measured. The magnitude, even the direction, of  $\gamma$ -deuterium isotope effects in noncyclic reactions is less readily predicted, and a definite answer to this question awaits experimental evidence.

With this background, we have initiated a program to evaluate these effects as mechanistic criteria for intramolecular allylic rearrangements by measuring the kinetic effect of  $\alpha$ - and  $\gamma$ -deuterium substitution on a reaction of known cyclic character. We chose to study the rearrangement of allyl thionbenzoate (I) to allyl thiolbenzoate (eq 3). Smith, who discovered this reac-

tion, showed that it was extremely insensitive to polar, solvent, and substituent effects and must, therefore, involve a cyclic rather than a carbonium ion mechanism.<sup>7</sup> Other considerations render carbanion or free radical reactions unlikely. For our purposes, this reaction also offered ready synthetic accessibility and a convenient method for kinetic determinations.

## Results

The required allyl-1,1- $d_2$  alcohol was prepared from acrylyl chloride and lithium aluminum deuteride according to the method of Schuetz and Millard.<sup>12</sup> After some exploratory experiments, the following route (eq 4) was worked out for the preparation of allyl-3,3- $d_2$

alcohol. The lithium aluminum hydride reduction of propargylic alcohols to allylic alcohols has been studied in some detail by Bates, Jones, and Whiting,<sup>13</sup> but this appears to be the first report of its use in the simplest case, propargyl alcohol itself. The deuterated allylic alcohols thus obtained were better than 99.2% homogeneous to capillary gas chromatography and had retention times undistinguishable from that of pure allyl alcohol. Their structures were further confirmed by infrared and nmr spectra. In particular in the infrared spectrum of the allyl-1,1- $d_2$  alcohol the  $\alpha$ -CH<sub>2</sub> stretching bands at 3.41 and 3.49  $\mu$  appear as CD absorptions at 4.55 and 4.78  $\mu$  and the CH<sub>2</sub> deformation at 6.89  $\mu$ <sup>14</sup> is replaced by a new band at 8.70  $\mu$  which is probably the CD<sub>2</sub> deformation. In addition, the nmr spectrum of this compound differs from that of allyl alcohol in that

doublet at  $\tau$  6.00 of the  $\alpha$ -methylene<sup>18</sup> proton is not and the ten-line pattern of the  $\beta$ -vinyl proton is simplified to the four-line X portion of an ABX spectrum with  $J_{AX}$  (*trans*) = 16 Hz and  $J_{BX}$  (*cis*) = 10 Hz. 1-3,3- $d_2$  alcohol similarly exhibits a shift of the terminal methylene absorptions at 3.25, 3.35, 7.10, 10.90  $\mu$  (CH) to 4.31, 4.51, 9.63, and 13.70  $\mu$  (CD) in the infrared. The nmr spectrum of this compound revealed the absence of the 4.67–5.10 multiplet of the terminal methylene in allyl alcohol; the weak perturbations of the  $\alpha$ -CH<sub>2</sub> doublet at  $\tau$  6.00 (long-range coupling) were gone and the  $\beta$ -vinyl resonance appeared as a broad hump at  $\tau$  4.12, presumably a triplet broadened by coupling to the deuterons on the  $\gamma$  carbon.

These alcohols, together with unlabeled allyl alcohol, were converted to the corresponding thionbenzoates by treatment with sodium hydride followed by benzoyl chloride.<sup>7</sup> The latter compound was prepared by the method of Staudinger and Siegmant<sup>19</sup> and purified by repeated distillation to constant nmr infrared spectra.

The allyl-1,1- $d_2$  thionbenzoate (II) thus obtained contained 1.98 D atoms per molecule and the isomeric 3,3- $d_2$  thionbenzoate (III) has 1.85 D atoms per molecule.<sup>17</sup> The infrared spectrum of allyl thionbenzoate (I) was in agreement with that reported by Smith,<sup>7</sup> and its nmr spectrum supported the assigned structure. It is perhaps worthy to note that the aromatic protons adjacent to the thiocarbonyl group in this series of compounds are deshielded relative to their counterparts in aryl benzoyl compounds by about 0.3 ppm. The spectra of the deuterium-substituted allyl thionbenzoates are also consistent with their assigned structures, exhibiting spectral features similar to those observed for corresponding alcohols.

The kinetic data recorded in Table I were obtained by the ampoule technique, following the disappearance of the thionbenzoate absorption at 410  $\mu$  in acetonitrile. Rate constants were calculated by the method of DeTar<sup>20</sup> and the best least-squares fit to the exponential form of the first-order rate equation (see Experimental Section). Standard errors in almost all cases were less than 0.8%, so that the 95% confidence limits for the individual rate constants are less than  $\pm 1.7\%$ . Isotope effects (rate ratios) are calculated for simultaneous deuterations on the three allyl thionbenzoates I–III. Isotope effects calculated for one deuterium atom at the  $\alpha$  position are:  $\alpha$ ,  $0.059 \pm 0.007$  and  $\gamma$ ,  $0.97 \pm 0.007$ . Activation parameters calculated for the rearrangement of the unlabeled compound, allyl thionbenzoate, are  $\Delta H^\ddagger = 25.7 \pm 0.6$  kcal/mole and  $\Delta S^\ddagger = -10$  cal/mole

and the effect of temperature on the deuterium isotope effect is so small that it is within the experimental error of our determinations. The slight increase in the magnitude of the  $\gamma$ -isotope effect is consistent with earlier results on thiocyanate ion catalyzed isomerization of maleic to fumaric acid but is not of itself statistically significant. Attempts to calculate  $\Delta\Delta H^\ddagger$

and  $\Delta\Delta S^\ddagger$  from these data by the method of Leffek, Robertson, and Sugamori<sup>19</sup> give values which are not statistically significant.

Samples of the reaction products, allyl thiolbenzoates, were obtained by treating samples of the allyl thionbenzoates I–III for 200 hr at 100° in sealed tubes.<sup>7</sup> Allyl thiolbenzoate was obtained from I, as indicated by the correspondence of its infrared spectrum with that reported by Smith and the agreement of its nmr spectrum with the assigned structure. Allyl-1,1- $d_2$  thionbenzoate (II) afforded the product of clean allylic rearrangement, allyl-3,3- $d_2$  thiolbenzoate, most clearly indicated by the absence of the  $\tau$  4.40–5.08 terminal methylene absorption in the nmr. Similarly allyl-3,3- $d_2$  thionbenzoate (III) gave allyl-1,1- $d_2$  thiolbenzoate as indicated by the absence of the  $\tau$  4.37 doublet ( $\alpha$ -methylene). We estimate that no more than 3–4% of unrearranged allyl moiety could have gone undetected in these experiments. These results agree with the conclusion of Smith that clean rearrangement of the allyl moiety accompanies conversion of the thion to the thiol ester.

## Discussion

The strongly negative entropy of activation provides strong support for the conclusion, reached earlier by Smith<sup>7</sup> on the basis of polar solvent and substituent effects, that this reaction proceeds by way of a cyclic transition state. Similar values of  $\Delta S^\ddagger$  have been observed for the Claisen and Cope rearrangements.<sup>4,6</sup> An alternate interpretation of large negative entropies of activation, electrostriction of solvent in a polar transition state, seems inapplicable here in view of the insensitivity of this reaction to solvent polarity.

The  $\alpha$ -deuterium isotope effect (6–7% rate retardation) for this cyclic reaction is about one-half that observed at similar temperatures for the effect of similar deuterium substitution on reactions involving carbonium ion, carbanion, or radical pathways.<sup>9,11</sup> This difference in magnitude is well beyond the experimental uncertainty involved. Since allylic rearrangements of noncyclic character can be expected to show normal  $\alpha$ -deuterium isotope effects (many of the "normal" reactions involve benzylic systems, electronically very similar to those involved in allylic noncyclic rearrangements), this result supports the hypothesis that  $\alpha$ -deuterium isotope effects are of real value in distinguishing between cyclic and noncyclic pathways for these rearrangements.

Deuterium analysis by J. Nemeth, Urbana, Ill.  
D. F. DeTar, *J. Am. Chem. Soc.*, **78**, 3911 (1956). We are indebted to a referee for calling this method to our attention and to the staff of the Washington State University Computing Center for invaluable assistance.

Similarly the rate acceleration (ca. 3% per deuterium) produced by deuterium substitution of the migration terminus is similar in magnitude and direction with several reactions in which some conversion of the trigonal carbon to tetrahedral has occurred at the transition state.<sup>9</sup>

This result may be compared to the  $\gamma$ -deuterium isotope effect of 1.00 ( $k_H/k_D$ ) reported by Belanić-Lipovac, Borčić, and Sunko<sup>20</sup> for the solvolysis of  $\alpha,\alpha$ -dimethylallyl chloride. The small, but real, difference in  $\gamma$ -deuterium isotope effect between the cyclic reaction studied here and this carbonium ion solvolysis supports the hypothesis that this type of effect also can be useful as a mechanistic criterion in such systems, provided that further experimental work supports the generality of these effects. From an empirical point of view, these conclusions must be regarded as tentative until supported by further experimental work with both cyclic and noncyclic rearrangements.

Viewed in a more theoretical light, these conclusions do not rest on particular assumptions used with Bigeleisen's fundamental equation for deuterium isotope effects.<sup>21</sup> If we adopt Streitwieser's assumptions, application of eq 5 from his early paper<sup>22</sup> on this subject indicates that a change of  $-65\text{ cm}^{-1}$  in the bending frequencies of the allyl thionbenzoate is responsible for the  $\gamma$ -deuterium effect upon going to the transition state. Similarly a change of  $135\text{ cm}^{-1}$  is associated with the  $\alpha$ -deuterium effect. Again, adopting Streitwieser's analysis of the important isotope vibrational frequencies,<sup>23</sup> the terminal methylene group in allylic compounds has been assigned frequencies of 3080, 2990, 1410, and  $920\text{ cm}^{-1}$ . Upon rearrangement these become, respectively, 2940, 2840, 1455, and  $1385\text{ cm}^{-1}$  in the  $\alpha$ -methylene compound, resulting in a total change of  $-325\text{ cm}^{-1}$  for the complete allyl thionbenzoate to allyl thiolbenzoate conversion. A similar change of  $+325\text{ cm}^{-1}$  is obtained for the deuterium-sensitive frequencies of the  $\alpha$ -methylene group. Insofar as these changes in vibrational frequencies reflect the structure of the transition state, the situation at both the  $\alpha$ - and  $\gamma$ -carbons resembles reactants more than products, with the change in frequencies somewhat more pronounced at the  $\alpha$ - than the  $\gamma$ -carbon. It is worth noting that this conclusion does not rest on a detailed correlation between vibration frequencies and bond order of the reacting bond at the transition state, but rather on the assumption that changes in bond strength are reflected in roughly proportionate changes in vibration frequency for the  $\alpha$ -CH bending modes.

Alternatively, if one adopts the formulation of Wolfsberg and Stern<sup>24</sup> in which bending force constants rather than vibrational frequencies are used as primary structural parameters, the same conclusion may be reached. In this way, one interprets the  $\gamma$  effect as

reflecting a small alteration of the carbon-hydrogen bending force constants at the transition state and the  $\alpha$  effect as involving a smaller alteration at this site than those commonly encountered or treated in Wolfsberg's model calculations. Insofar as bending force constants reflect structure, then, the same conclusion regarding placement of the transition state along the reaction coordinate is reached. The validity of this argument also does not rest on a relationship between force constants and bond order in the "reacting" bonds, although it seems reasonable to believe that the length of this bond in the transition state will influence the steric environment of the neighboring carbon-hydrogen bonds enough to alter the bending force constants.

Further, the transition state for this reaction may be described as "looser" than completely concerted in that bond breaking at the  $\alpha$ -carbon appears to be more advanced than bond formation at the  $\gamma$ -carbon. This involves the assumption, reasonable but not firmly established, that the functional relationships between bond order in the bond-breaking process and the  $\alpha$ -deuterium isotope effects are the same as those operating between the bond-making process and the  $\gamma$ -deuterium isotope effect. In this light, the fact that the  $\gamma$ -deuterium isotope effect is smaller than the  $\alpha$  effect implies that bond making at the  $\gamma$ -carbon is lagging behind bond breaking at the transition state. *A posteriori*, this is reasonable since the conversion of reactant to transition state is an endothermic process and in a unimolecular reaction devoid of strong solvation effects it must involve a decrease in total bond order. This takes no account, of course, of over-all bond order changes internal to the allyl and thiocarboxyl moieties, which may well play a significant role in the activation process.

The pattern of deuterium isotope effects observed here is consistent with a transition state which more closely resembles reactant (allyl thionbenzoate) than product (allyl thiolbenzoate). This interpretation, which is consistent with Hammond's postulate<sup>25</sup> for a one-step exothermic reaction, does not depend on a particular set of approximations used in interpreting deuterium isotope effects, as discussed above, and raises the intriguing possibility that measurement of these effects in reactions of known cyclic character can lead to placement of their transition states along a reactant-product reaction coordinate. We are presently testing this hypothesis on such cyclic allylic rearrangements.

## Experimental Section

**Thiobenzyl Chloride.** This material was prepared by the method of Staudinger.<sup>14</sup> Repeated distillation removed impurities exhibiting absorptions at  $\tau$  2.17–2.40 in the nmr and 12.6 and  $14.2\text{ }\mu$  in the infrared. The purified material was deep purple in color and had bp  $53\text{--}55^\circ$  ( $0.2\text{ mm}$ );  $\lambda_{\text{max}}^{\text{nmr}}$  8.07 (s), 9.56 (s), 11.93 (s), 13.18 (s), 14.81 (s), and  $15.70\text{ }\mu$ ; nmr multiplets at  $\tau$  1.86–2.08 (2 H, *ortho*) and  $\tau$  2.48–3.08 (3 H, *meta* and *para*);  $\lambda_{\text{max}}^{\text{nmr}}$  527 m $\mu$  ( $\epsilon$  68).

**Allyl-1,1- $d_2$  Alcohol.** This material was prepared by the method of Schuetz and Millard,<sup>15</sup> bp  $92\text{--}95^\circ$  ( $690\text{ mm}$ );  $\lambda_{\text{max}}^{\text{nmr}}$  3.00 (broad, s), 4.55 (m), 4.78 (s), 7.09 (s), 8.38 (s), 9.10 (s), 10.04 (s), 10.40 (s), and  $10.80\text{ }\mu$ ; nmr absorptions at  $\tau$  3.86–4.31 (1 H, quadruplet,  $J_{AX} = 16\text{ Hz}$ ,  $J_{BX} = 10\text{ Hz}$ ),  $\tau$  4.67–5.10 (2 H, two overlapping AB quadruplets,  $J_{AX}$  and  $J_{BX}$  as above,  $J_{AB} = -2\text{ Hz}$ ), and  $\tau$  5.30 (1 H, singlet); no detectable absorption at  $\tau$  6.0 ( $\alpha$ -CH<sub>3</sub>).

(23) It is recognized that this approach is somewhat deficient in the absence of a complete assignment of the vibrational frequencies of those compounds (see ref 9). However, these assignments are supported by the observed shifts in our deuterium-substituted allylic compounds and are in accord with previous work (ref 14; also, L. J. Bellamy, "The Infrared Spectra of Complex Molecules," John Wiley and Sons, Inc., New York, N. Y., 1958, pp 13, 34).

(24) M. Wolfsberg and M. J. Stern, *Pure Appl. Chem.*, **8**, 325 (1964).

**Propargyl-3,0- $d_2$  Alcohol.** Propargyl alcohol (11.2 g, 0.20 mole) was equilibrated with 20 g of  $D_2O$  containing 6 mg of barium oxide overnight. The mixture was continuously extracted with 15 ml of ether for 6 hr, and the ether layer was stirred overnight with 20 g of fresh  $D_2O$  containing 35 mg of BaO. The latter equilibration was repeated twice more, and the final ether extract was dried and distilled in a micro spinning-band column affording 8.16 g of propargyl-3,0- $d_2$  alcohol, bp 108–110° (690 mm), homogeneous to capillary gas chromatography. Spectral analysis showed: nmr <1%  $\tau$  7.29 ( $C\equiv CH$ ), ca. 10%  $\tau$  5.37 (OH),  $\tau$  5.75 ( $CH_2$ , singlet);  $\lambda_{max}^{OH}$  3.00 (OH, m), 3.86 (CD, s), 4.03 (OD, m), 5.04 (m), 7.36 (m), and 9.78 (m)  $\mu$ .

**Allyl-3,3- $d_2$  Alcohol.** Propargyl-3,0- $d_2$  alcohol (8.0 g, 0.14 mole) dissolved in 100 ml of dry ether was added dropwise under a nitrogen atmosphere to a slurry of lithium aluminum hydride (5.7 g, 0.15 mole) in 70 ml of ether maintained at 4–6° in an ice bath. After the addition was complete (85 min), the reaction mixture was stirred at 0° for 12 hr when gas chromatographic examination of a quenched aliquot showed that the reduction was 95% complete and that less than 0.3% of propyl alcohol had been produced. Deuterium oxide (12 ml) was cautiously added, and the mixture was stirred for 14 hr when 9.6 ml of 10% aqueous NaOH solution was added. The precipitated inorganic solids were removed by filtration and washed well with ether. The combined filtrates and washings were distilled in a micro spinning-band column affording 2.88 g of allyl-3,3- $d_2$  alcohol, bp 92–94° (695 mm), containing less than 0.2% propyl alcohol and less than 0.6% propargyl alcohol by capillary gas chromatography. Spectral analysis showed:  $\lambda_{max}^{OH}$  3.00 (broad, OH), 3.49 ( $CH_2$ , m), 4.05 (broad, OD), 9.10 (m), 9.91 (s), 13.70 (m)  $\mu$ ; nmr absorptions (in  $\tau$ ) at 4.12 (1 H, broad), 3.98 (2 H, doublet,  $J = 5$  Hz), and 6.78 (OH, 0.6 H, singlet), negligible absorption at 4.87 ( $\delta-CH_2$ ).

**Allyl Thionbenzoate and Its Deuterated Analogs.** These compounds were prepared from the appropriate allyl alcohol and thionbenzoyl chloride by the method of Smith. The spectra of all three allylic thionbenzoates had the following common features:  $\lambda_{max}^{cyclohexane}$  420 m $\mu$  ( $\epsilon$  122);  $\lambda_{max}^{OH}$  3.26 (w), 6.27 (w), 6.90 (w), 7.60 (s), 7.92 (s), 8.20 (s), 9.30 (m), 9.52 (m), 9.76 (m), 10.72 (m), 12.98 (m), 14.60 (s), and 15.76 (m)  $\mu$ ; nmr absorptions at  $\tau$  1.75–1.98 (2 H, *ortho*, multiplet) and  $\tau$  2.62–3.02 (3 H, *meta* and *para*, multiplet). In addition, allyl thionbenzoate had  $\lambda_{max}^{OH}$  10.10 (w), 10.90 (w)  $\mu$ ; and nmr absorptions at  $\tau$  3.65–4.34 (1 H,  $\beta$ -proton, multiplet),  $\tau$  4.53–4.95 (2 H,  $=CH_2$ , multiplet), and  $\tau$  4.97 (2 H,  $CH_3$ , weakly perturbed doublet,  $J = 6$  Hz, overlapping  $=CH_2$  peak).

**Anal.**<sup>26</sup> Calcd for  $C_8H_{10}OS$ : C, 67.38; H, 5.66; S, 17.99. Found: C, 67.63; H, 5.80; S, 17.74.

Allyl-1,1- $d_2$  thionbenzoate had, in addition,  $\lambda_{max}^{OH}$  4.50 (w), 4.70 (w), 7.10 (m), and 10.90 (m)  $\mu$ , and showed nmr absorptions at  $\tau$  4.02 (center of gravity, 4 lines,  $J_{AX} = 17$  Hz,  $J_{BX} = 10$  Hz, 1 H) and  $\tau$  4.54–4.95 (multiplet, 2 H,  $=CH_2$ ). Allyl-3,3- $d_2$  thionbenzoate had, in addition,  $\lambda_{max}^{OH}$  4.31 (w), 11.20 (w), and 13.40 (m)  $\mu$ , and showed nmr absorptions at  $\tau$  4.08 (broad, 1 H, half-height width 13 Hz) and  $\tau$  5.01 (doublet,  $J = 6$  Hz, 2 H).

**Kinetic Measurements.** Rates were followed by the ampoule technique, 13 separate observations between 10 and 85% reaction being made in most runs. Three simultaneous kinetic determinations were made on allyl thionbenzoate (I) and its deuterated analogs II and III. Solutions were made up by accurately weighing the appropriate thionbenzoate into a 50-ml volumetric flask and diluting to the mark with spectro grade acetonitrile. Aliquots (3.3 ml) were transferred to Pyrex ampoules which were immediately sealed. Care was taken to randomize the order in which ampoules were sealed and later removed from the constant temperature bath.

The ampoules were weighted with lead strips and placed in a wire mesh basket. The basket was placed in the constant temperature bath (controlled to 0.02° by a proportioning controller) and allowed to come to thermal equilibrium for 30–60 min. To start each run, other ampoules were similarly withdrawn and quenched at appropriate intervals to obtain each kinetic point. An ampoule was withdrawn and immediately quenched in ice-acetone. Control experiments showed that the temperature dropped more than 20° within 5 sec. The quenched ampoules were stored in the refrigerator at –5° until the run was completed. Infinity points were

obtained after 10–12 half-lives at 100° and were about 2% of the initial absorption.<sup>27</sup> Before measuring the absorbance the ampoules were allowed to warm to room temperature. The absorbance at 410 m $\mu$  was read from the 520 to 350 m $\mu$  spectrum of the sample determined on a Cary Model 14 spectrophotometer. Duplicate determinations were reproducible to 0.003 absorbance unit.

Following the method of DeTar,<sup>18</sup> the rate constants were determined by fitting the data to the equation  $A = a + be^{-kt}$ , where  $A$  is the absorbance at time  $t$ ,  $a$  is the absorbance at infinite time, and  $b = A_0 - A_\infty$ . The initial estimates of  $a$  and  $b$  required by this method were measured values and the initial estimate of  $k$  was obtained from a least-squares fit of the data to the equation  $\ln(A - A_\infty) - \ln(A_0 - A_\infty) = -kt$ . Table II contains data for a typical run, including a comparison of observed absorbances and those calculated from the parameters obtained from the exponential least-squares fit. The standard deviations of most rate constants were less than 0.8%, and calculated initial and infinity absorbances were within 0.01 absorbance unit of those observed. Temperatures were measured by a National Bureau of Standards calibrated thermometer.

Table II. Data for a Typical Kinetic Run<sup>a</sup>

46,755	0.161	0.159
$\infty$	0.022	0.022

<sup>a</sup> Initial estimate:  $A = 0.0220 + 1.1090 \exp(-0.000044644t)$ ; final parameters:  $A = 0.0220 + 1.1125 \exp(-0.000044755t)$ .

**Reaction Products.** Samples (ca. 150 mg) of allyl thionbenzoate and the two deuterium-substituted allyl thionbenzoates were sealed in small glass ampoules and immersed in the 100° oil bath for 200 hr (more than ten half-lives for the slowest reaction rate reported). The products were characterized as follows. Allyl thionbenzoate gave allyl thiolbenzoate:  $\lambda_{max}^{cyclohexane}$  420 m $\mu$  ( $\epsilon$  1.2);  $\lambda_{max}^{OH}$  3.27 (w), 3.41 (w), 6.02 (s), 6.32 (m), 6.91 (m), 8.30 (s), 8.51 (s), 10.14 (m), 11.00 (s), 12.97 (s), 14.56 (s), and 15.47 (s)  $\mu$ ; nmr absorptions at  $\tau$  2.02–2.25 (multiplet, 2 H, *ortho*), 2.51–2.75 (multiplet, 3 H, *meta* and *para*), 3.80–4.50 (multiplet, 1 H,  $\beta$ ), 4.40–5.08 (multiplet, 2 H,  $\delta$ ), and 6.37 (doublet,  $J_{app} = 7$  Hz, 2 H,  $\alpha$ ). Allyl-1,1- $d_2$  thionbenzoate gave allyl-3,3- $d_2$  thiolbenzoate:  $\lambda_{max}^{cyclohexane}$  420 m $\mu$  ( $\epsilon$  1.6);  $\lambda_{max}^{OH}$  as in allyl thionbenzoate except that the 10.14- $\mu$  band was absent; bands at 4.31 (w), 4.51 (w), and 13.60 (m)  $\mu$ ; nmr absorptions as in allyl thiolbenzoate except that  $\tau$  4.40–5.08  $\delta$ -hydrogen absorption and weak perturbations of the  $\tau$  6.37 doublet were absent, and the  $\tau$  3.80–4.50 multiplet had collapsed to a broad absorption centered at  $\tau$  4.19, half-height width 14 Hz. Allyl-3,3- $d_2$  thionbenzoate gave allyl-1,1- $d_2$  thiolbenzoate;  $\lambda_{max}^{cyclohexane}$  420 m $\mu$  ( $\epsilon$  1.6);  $\lambda_{max}^{OH}$  as in allyl thionbenzoate except that the 3.42- $\mu$  band is absent and an absorption at 4.64 (w)  $\mu$  is present; nmr as in allyl thionbenzoate except that the  $\tau$  3.80–4.50 multiplet has collapsed to a four-peak pattern centered at  $\tau$  4.17 ( $J_{AX} = 16$  Hz,  $J_{BX} = 10$  Hz), the  $\tau$  4.40–5.08 multiplet is simplified to an eight-line pattern centered at  $\tau$  4.92 ( $J_{AX}$  and  $J_{BX}$  as above,  $J_{AB}$  probably –2 Hz), and the  $\tau$  4.37 doublet was absent.

## Secondary Deuterium Kinetic Isotope Effects in Radical-Forming Reactions. II. The Decomposition of *t*-Butyl Perpivalate

T. Koenig and R. Wolf<sup>1</sup>

Contribution from the Department of Chemistry, University of Oregon, Eugene, Oregon 97403. Received December 6, 1966

**Abstract:** Measurement of the rates of decomposition of *t*-butyl perpivalate and its deuterated analog show the secondary deuterium kinetic isotope effect on the formation of *t*-butyl radical is 1.02 per deuterium. The theories proposed to explain these isotope effects are compared using the present data and that for the formation of *t*-butyl cation.

While the effect of substitution of deuterium for hydrogen on the rates of a large number<sup>2</sup> of reactions leading to cationic intermediates have been determined, almost no attention has been given to these effects in radical-forming processes. The earliest report of such an isotope effect in a radical reaction was that for the autoxidation of cumene which indicated the magnitude of  $k_H/k_D$  to be 1.10.<sup>3</sup> The effects have also been measured<sup>4</sup> for radical addition to olefins but the interpretation in these cases is complicated by opposing  $\alpha$  and  $\beta$  effects which operate simultaneously. In a study directed mainly at determining the magnitude of  $\alpha$  isotope effects in concerted acyl peroxide cleavage, a preliminary measurement of the effect of partial  $\beta$  deuteration on the rate of decomposition of *t*-butyl perhydratropate was also reported.<sup>5</sup> Here the isotope effect was found to be quite small ( $k_H/k_D \sim 1.02$ ). This small<sup>6</sup> isotope effect for the formation of  $\alpha$ -phenethyl radical in the converted decomposition of the corresponding perester was at odds with that reported for the formation of cumyl radical and also at odds with some theories<sup>2</sup> of the origin of these isotope effects in general. It was thus decided to measure the  $\beta$  deuterium secondary kinetic isotope effect on the formation of *t*-butyl radicals in the decomposition of *t*-butyl perpivalate.

It has previously been shown<sup>7</sup> that the decomposition of this compound is concerted. Therefore, *t*-butyl radical character is present in the over-all rate-determining transition state. Since nine deuterium atoms can be incorporated, a reduction in the relative error of the measurements was anticipated. In addition, a comparison of the isotope effects for formation of radicals and cations of the same formal structure should be helpful in providing a distinction between the theories proposed to account for these isotope effects. The isotope effect on the solvolysis of *t*-butyl chloride has been determined by several groups.<sup>8</sup>

While these studies were in progress, a report of the  $\beta$  isotope effect on the formation of  $\alpha$ -phenethyl radical in the decomposition of the corresponding azo compound appeared.<sup>9</sup> The isotope effect observed in this case was in agreement with that estimated for the decomposition of the perhydratropate but with greatly increased accuracy.

### Results

Deuterated pivalic acid was obtained from *t*-butyl chloride- $d_4$  by a Grignard sequence. The peresters were obtained by the Bartlett<sup>7</sup> method and purified by column chromatography. Their deuterium content was estimated by a quantitative nmr technique. Purity was judged by their nmr and infrared spectra and by reproducibility of the rate constants upon repurification.

The rates were measured in purified solvents by disappearance of the infrared carbonyl adsorption ( $k_{IR}$ ) at  $1772\text{ cm}^{-1}$  and by pseudo-first-order<sup>10</sup> and zero-order disappearance<sup>11</sup> of galvinoxyl ( $k_G$ ) using its visible absorption at  $770\text{ m}\mu$ . The results of these studies are summarized in Table I.

The stated errors are for *completely reproduced* experiments in which each compound was resynthesized from a different batch of *t*-butyl chloride. Decompositions in different batches of purified solvent and the decomposition of the undeuterated perester obtained from a commercial batch of pivalic acid all showed rate behavior within the stated uncertainty. The rate constants were obtained from a linear least-squares treatment of the data.<sup>12</sup> All rate plots were linear for at least three half-lives.

The rate constants obtained by the infrared method were invariably higher than those observed by the galvinoxyl method. Both the presence of a good radical scavenger and the low perester concentrations used in the galvinoxyl method should tend to decrease the relative importance of any radical-induced paths for destruction of perester. The difference in the rates obtained by the two methods might, therefore, be a consequence of some induced decomposition remaining

assuming a  $k_0$  of  $4.188 \times 10^{-4}$  sec<sup>-1</sup>.

the conditions of the infrared measurement. Data of Table II support this interpretation. Clearly defined increase in  $n$ , the moles of radicals produced/mole perester consumed, with decreasing initial perester concentration was observed by the zero-order<sup>11</sup> oxyl method. Since the products of the reaction include a large amount of polymer, the details of this alcohol-induced path are obscured. However, we use the data of Table II establish that such a path exists and therefore that the galvinoxyl rates are more likely correct. The intervention of such a radical-induced path would tend to decrease the isotope effect and is isotopically insensitive. This would explain the lower magnitude of the isotope effect obtained by infrared method.

The gaseous products of the decomposition were identified briefly, and the results are summarized in Table III.

## III. Gaseous Products of Decomposition at 60.56°

Product	Yield, moles/mole	
	Chlorobenzene	90% aqueous dioxane
Carbon dioxide	0.908	0.874
Isobutane	0.134	0.381
Isobutylene	0.109	0.477
Methane	0.103	0

chlorobenzene, the yields of carbon dioxide, isobutane, and isobutylene are comparable to those reported previously.<sup>7</sup> The yields of these hydrocarbons are higher in the aqueous dioxane. The *t*-butyl alcohol produced from decomposition of the deuterated perester in aqueous dioxane was shown to contain no deuterium, indicating that none of the ionic processes such as

carboxy inversion<sup>13</sup> or *t*-butyl cation formation<sup>14</sup> are likely in this case.

## Discussion

The results of the preceding section indicate that  $k_{H_2}/k_{D_2}$  for the formation of *t*-butyl radical from the corresponding perester is 1.02. This value is slightly higher than that observed for the formation of  $\alpha$ -phenethyl radical ( $k_{H_2}/k_{D_2} = 1.017$ ) in the decomposition of the corresponding azo compound.<sup>8</sup> Though the isotope effect is small, it is much larger than effects calculated for transition states which do not involve perturbations of the C-H force constants.<sup>9,15</sup> It is, however, much smaller than the effect ( $k_{H_2}/k_{D_2} \sim 1.11$ ) observed for formation of *t*-butyl cation under a variety of conditions.<sup>8</sup> The fact that the isotope effect is nearly the same in the more basic aqueous dioxane shows the polar character, necessitated for the transition state of concerted decomposition of ring-substituted *t*-butyl perphenylacetates ( $P = -1.09$ ),<sup>16</sup> is apparently not pronounced enough to cause carbonium ion type isotope effect to be admixed in this case. This result is in accord with the small solvent effect on the over-all rate of decomposition. The data at the second temperature in chlorobenzene indicate the small observed isotope effects are not a result of proximity to an isokinetic temperature.

**Theories of the  $\beta$  Effect.** Though these isotope effects have been known for a number of years, there is no general agreement on the details of their origin. The theories proposed to explain them include pure steric effects,<sup>17</sup> large decrease in C-H bending frequency in the hyperconjugatively stabilized transition states,<sup>18</sup> decreased stretching frequency in the hyperconjugatively stabilized transition states,<sup>19</sup> hyperconjugative effects plus solvation,<sup>20</sup> and decreased zero-point energy due to hyperconjugation and anharmonicity.<sup>21</sup> The latter theory is a quantitative one in which isotope effects have been identified with the loss in resonance energy due to the decrease in the average C-D bond length

and bond angle as calculated by molecular orbital methods.<sup>22</sup>

Most of these theories have the concept of hyperconjugative stabilization of radicals and cations as a common beginning point. In order to compare the predictions of these various theories for radical- and cation-forming processes, molecular orbital calculations for the ethyl, isopropyl, and *t*-butyl radicals and cations were carried out using essentially the parameterization of Colpa and DeBoer.<sup>23,24</sup> In these calculations, the three hydrogen 1s and methyl carbon atomic orbitals are transformed into pseudo-group orbitals, one of which, in each case, has the proper symmetry for linear combination with the 2p vacancy at the central carbon.

$$\begin{array}{lll} \alpha_1 = \alpha_0 - 0.5\beta_0 & S_{12} = 0.500 & \beta_{12} = S_{12}/S = 2.00\beta_0 \\ \alpha_2 = \alpha_0 - 0.1\beta_0 & S_{23} = 0.190 & \beta_{23} = S_{23}/S_0 = 0.76\beta_0 \\ \alpha_3 = \alpha_0 & & \omega = 1.41 \end{array}$$

The results of the calculations with these parameters, are summarized in Table IV.

Table IV. Molecular Orbital Results

Species	DE <sup>a</sup>	$\Delta DE^b$	Den. <sup>c</sup>	$\Delta P_{12}^d$	$\pi_{12,12}^e$	$k/k''$
C <sub>2</sub> H <sub>5</sub> <sup>+</sup>	0.6967	216	0.592	0.072	0.454	1.96
C <sub>2</sub> H <sub>5</sub> ·	0.1025	54	0.860	0.025	0.077	1.11

<sup>a</sup> The delocalization energy in units of  $\beta_0$ , the bond integral for benzene. <sup>b</sup> Decrease in delocalization energy (in cal/mole) for the deuterated compound due to increased  $S_{12}$  assuming  $\beta_0 = 60$  kcal/mole. <sup>c</sup> Spin or positive charge density at the central carbon for the radicals or cations, respectively. <sup>d</sup> Decrease in bond order per C-H bond, i.e.,  $1 - [(2 + P_{12})/3]$ . <sup>e</sup> Self-polarizability of the  $\pi$  C=H bond. <sup>f</sup> Total calculated isotope effect for the fully  $\beta$ -deuterated intermediates at 300°K.

Ideally, these calculations should predict the resonance energy and spin density for the radicals and resonance energy and charge density for the cations. The calculated resonance energy is in fair agreement with experiment<sup>27</sup> for the radicals, but somewhat low for the cations in the gas phase assuming  $\beta_0$  is 60 kcal/mole. The delocalization of both spin<sup>28</sup> and charge appears to be overemphasized when compared to esr<sup>29</sup> and nmr<sup>30</sup> results for the species in solution.<sup>31</sup>

(22) We are grateful to Professor Halevi for helpful discussions concerning the interpretation of his theory.

(23) J. P. Colpa and E. DeBoer, *Mol. Phys.*, **7**, 333 (1963).

(24) An excursion into the variation in parameters and methods of iteration including those of Chesnut,<sup>25</sup> Halevi,<sup>31</sup> and Mulliken<sup>26</sup> indicates none of the conclusions made here would be significantly altered by a different choice.

(25) D. B. Chesnut, *J. Chem. Phys.*, **29**, 43 (1958).

The calculated changes in resonance energy for the deuterated intermediates, listed in the third column of the table, are arrived at by increasing  $S_{12}$  by 0.0025 according to the arguments of Halevi<sup>2,21</sup> but without consideration of the inductive effect of deuterium. The change for the *t*-butyl radical is close to the observed isotope effect. The similarity calculated by this method for the radical- and cation-forming processes is, however, too great even without consideration of the greater electropositivity of deuterium.<sup>32</sup>

In order to examine the molecular orbital predictions of the relative isotope effects due to changes in vibrational frequency, several assumptions are necessary. (a) Streitwieser's<sup>18</sup> simplification of the complete equation for calculation of isotope effects in terms of vibrational frequencies is used.

$$\ln k_H/k_D = (0.187/T)\Sigma(\nu - \nu^*) \quad (1)$$

(b) The differences between transition and intermediate states and between gas phase and solution are neglected in the beginning but discussed later. (c) The drastic<sup>33</sup> assumption is made that all of the vibrational frequencies which are important in determining the magnitude of the isotope effect will vary in proportion to the change in the C-N stretching force constant. This last assumption allows a simplification of (1) to

$$\ln k_H/k_D = (0.187/T)\Delta\gamma_{\text{eff}} \quad (2)$$

where  $\Delta\gamma_{\text{eff}}$  is the effective frequency change on going from initial to transition state which is assumed to be proportional to the change in force constant for C-H stretching. The problem now becomes one of relating the molecular orbital wave functions to change in force constant for C-H stretching since

$$\Delta\gamma_{\text{eff}} = \gamma_{\text{eff}}(1 - \sqrt{F'/F_0})$$

where  $\gamma_{\text{eff}}$  is an effective frequency and  $F'$  and  $F_0$  are the force constants for the C-H stretching in the transition and beginning states, respectively.

It can be seen immediately that the isotope effects for the radical- and cation-forming processes will be too similar in magnitude if one assumes the changes in force constants to be proportional to changes in bond order.<sup>34</sup> Salem<sup>35</sup> has shown, in fact, that the bond order terms for changes in force constants cancel and that the actual changes should be proportional to the self-polarizability of the bond. Adapting this method to the present problem gives

$$F'/F_0 = 1 + C\pi_{12,12}\beta_0 \quad (3)$$

(31) Application of Simpson's truncated perturbation method to these molecules, parameterizing with the measured resonance energies and estimated heats of formation of the ethyl radical and cation structures, gives charge and spin densities which are very close to those calculated here. This method, however, predicts no electronic transitions for the *t*-butyl cation below 220 mμ: W. T. Simpson and C. W. Looney, *ibid.*, **76**, 6285 (1954).

(32) A more refined version of this type of calculation gives better agreement: S. Ehrenson, private communication.

(33) In general, this is indeed a drastic assumption, but in terms of molecular orbital theory, it has some merit. For example, as the C≡H  $\pi$  bond weakens, the C-C  $\pi$  bond must strengthen. The effect also appears to be dominated by the stretching mode change.

The infrared spectrum of *t*-butyl cation in solution has recently been measured and a normal mode analysis carried out.<sup>30</sup> The set of frequencies obtained from this analysis predicts an equilibrium isotope effect for formation of the cation which is nearly identical with the kinetic isotope effect observed for the solvolysis of *t*-butyl chloride.<sup>36</sup> These data provide a method of parameterizing eq 3 so that self-polarizability can be used to predict secondary isotope effects. The  $F'/F_0$  ratio used in this normal mode analysis is 0.885 and  $k_H/k_D$  for solvolysis of *t*-butyl chloride at 25° is 2.38. These data give

$$\ln k_H/k_D = (482/T)(1 - \sqrt{1 - 0.572\pi\beta}) \quad (4)$$

where the constants have been taken into account and  $\pi$  is the self-polarizability of the  $C\equiv H$ ,  $\pi$  bond. The last column of Table IV gives the calculated isotope effect of all the compounds shown using this parameterization. The observed total isotope effect for formation of the *t*-butyl radical is very close to the value calculated here.

The relatively small isotope effect now established for radical formation is thus in agreement with the extent to which hyperconjugation stabilizes such molecules. The calculated self-polarizability of the  $C\equiv H$ ,  $\pi$  bond in the  $\alpha$ -phenethyl radical is nearly identical with that for *t*-butyl and thus an identical isotope effect would be predicted by the present theory. We believe the lower value for this isotope effect observed by Seltzer is due to a decrease in the relative endothermicity of azo compound compared to perester decomposition and that the isotope effect in the perhydratropate decomposition will be closer to that observed for the pervalate. This point is being tested presently.

The good quantitative agreement for the *t*-butyl radical and cation systems should be viewed cautiously because of the assumptions made. Two complications with assumption b are apparent. One is the difference in degree of planarity of the transition states for radical and cation-forming processes. Preliminary calculations using the extended Hückel method<sup>37</sup> indicate that the isotope effect should be reduced for nonplanar transition states. These calculations also indicate that radicals experience relatively less stabilization on planarization than do carbonium ions. The importance of this possibility is being examined by studies of bridged compounds.

Alternatively, it can be argued that the isotope effect for radical reactions should be more nearly calculable by molecular orbital theory since radical reactions in solution are not very different from the corresponding process in the gas phase. The calculated charge density on the central carbon of isopropyl cation is less than that estimated from its nmr spectrum<sup>30</sup> taken under conditions quite similar to those for the infrared measurements which in turn were fit by the normal mode analysis. Thus, calculated delocalization is greater than observed for carbonium ions so that an underestimate of the isotope effect for the radical process should have resulted from parameterization using carbonium ion data.

(36) J. C. Evans and G. Y. -S. Lo, *J. Am. Chem. Soc.*, **88**, 2118 (1966).

(37) R. Hoffman, *J. Chem. Phys.*, **39**, 1397 (1963). The program for these calculations was the one obtainable from Quantum Chemistry Program Exchange with minor modifications.

This situation is resolved if the solvent is postulated to furnish an attractive interaction with the polarized  $\beta$  protons of the hyperconjugatively stabilized carbonium ion. The consequent broadening of the vibrational potential for these C-H bonds would result in a lowering of the effective force constant when considering the cations as independent entities. This is essentially a restatement of the effect as described by Shiner<sup>20</sup> and one which can be tested since its logical consequence is a similar isotope effect for cation formation in the gas phase. This argument could explain the relative insensitivity of the isotope effects for *t*-butyl cation formation in different solvents.

While we favor the last hypothesis as the best single explanation for  $\beta$  isotope effects in cation formation, the very approximate nature of the present treatment makes the argument considerably less than compelling. A more reasonable view is that the net isotope effects can be a result of several of the postulated origins. However, we would hope that the present treatment might be useful as an empirical guide to the expected magnitudes of such isotope effects. Accordingly, Table IV contains calculated isotope effects for each species and these predictions are presently being tested.

The steric origin<sup>17</sup> of these isotope effects has been neglected here. The argument that these effects are due to inordinately large changes in bending frequency<sup>18</sup> has also been neglected (a breakdown of assumption c). The infrared spectrum of the *t*-butyl cation showed no particular indication of this origin.

## Experimental Section

Proton nuclear magnetic resonance spectra were determined on a Varian A-60 spectrometer. Infrared measurements were made using a Beckman IR-7 instrument. Ultraviolet and visible spectral measurements were made on Cary 14 or Cary 11 spectrophotometers. Mass spectra were determined using a modified Consolidated Electrodynamics 26-614 residual gas analyzer.<sup>38</sup> Gas-liquid partition chromatography was carried out using an Aerograph Autoprep instrument.

**Materials.** Chlorobenzene was purified by shaking with 98% sulfuric acid, then with water, and drying over magnesium sulfate followed by a 2-hr reflux over phosphorus pentoxide. Finally, it was distilled from phosphorus pentoxide and then from potassium hydroxide, bp 130.5–130.9°.

Dioxane (reagent grade) was passed through a column of Woelm neutral alumina, refluxed over sodium for 24 hr, distilled, and passed through a column of neutral alumina. It was used immediately to prepare the 90% dioxane-water solutions which were stored in the dark, under nitrogen, at 0° until used.

*t*-Butyl hydroperoxide (Matheson Coleman and Bell) was distilled with the first third being discarded. The second third was retained, bp 32–35° (15 mm).

Galvinoxyl was prepared by the method of Kharasch.<sup>39</sup> Purification was by recrystallization in small amounts of absolute ethanol under nitrogen to a constant extinction coefficient of 595 at 776 m $\mu$  in benzene solution (lit.<sup>40</sup> 607 m $\mu$ ). Pivalic acid was obtained from Matheson Coleman and Bell.

**Peresters.** The peresters were prepared from the corresponding acid chlorides by the method of Bartlett.<sup>7</sup> Pivalic acid-*d*<sub>4</sub> was obtained by a Grignard sequence.<sup>41</sup> The pivaloyl chloride was obtained by adding 90% of the calculated equivalents of thionyl chloride to the pivalic acid. After refluxing for 0.5 hr, a small aliquot was removed and the acid content determined by its nmr spectrum. Small increments of thionyl chloride were added until

(38) Funds for the purchase of this instrument were partially furnished through grants from the National Science Foundation and National Institutes of Health.

(39) M. Kharasch and B. Joshi, *J. Org. Chem.*, **22**, 1435 (1957).

(40) P. D. Bartlett and T. Funahashi, *J. Am. Chem. Soc.*, **84**, 2956 (1962).

(41) A. Streitwieser and H. S. Klein, *ibid.*, **85**, 2159 (1963).

the acid chloride/acid ratio was greater than 20. The acid chloride was then used directly for the perester synthesis.

The peresters were purified by passing them through a column of Woelm activity 1 basic alumina at 0° using ether eluent. This effectively removes all traces of *t*-butyl hydroperoxide. Before each kinetic run the compounds were rechromatographed and all traces of ether removed by pumping under high vacuum. Peroxide contents as determined by iodometric titration were not reproducible (83–92%). A purity of 100% was assumed on the basis of the nmr and infrared spectra and the reproducible kinetic behavior.

The pivalic acid-*d*<sub>4</sub> and pivaloyl chloride-*d*<sub>4</sub> were shown to contain less than 1% hydrogen using the nmr spectrum of a solution containing weighed amounts of compound and dioxane. The perester contained less than 2.6% hydrogen in the pivaloyl fragment as judged by the total nmr peak areas in the *t*-butyl region compared to dioxane in known concentration.

**Kinetic Methods.** The infrared method for measuring the rates utilized the disappearance of the carbonyl stretching band of the perester at 1772 cm<sup>-1</sup>. The products of the reaction do not absorb at this frequency. Beer's law behavior was verified for this solvent-perester system. About 0.1-ml aliquots of about 0.1 *M* solutions of perester were added to 15 small tubes of Pyrex glass. The tubes were sealed and immersed in a constant temperature bath regulated to ±0.03°, removed at timed intervals, and quenched in ice. The tubes were stored at 0° until the infinity points were taken (ten half-lives). The analyses for duplicate runs were carried out together.

The pseudo-first-order galvinoxyl method utilized the disappearance of the galvinoxyl absorption at 767 mμ. The galvinoxyl solutions (10<sup>-3</sup> *M*) containing less than a radical equivalent (*n* × perester concentration) in Pyrex culture tubes were carefully degassed and sealed under vacuum. Beer's law behavior and the effective path length were determined for each tube. The reaction

tubes were immersed in the oil baths for timed intervals, removed and quenched, read in the spectrophotometer, and reimmersed in the bath for a new time increment. Blank solutions of galvinoxyl in chlorobenzene were completely stable over the length of the runs. The blank galvinoxyl solutions in aqueous dioxane showed 14% decomposition over the eight half-life time periods. The runs in this solvent were therefore corrected, point by point, for the behavior of the blank solution. All of the rate plots were linear for more than three half-lives. The zero-order galvinoxyl studies were the same except for the initial perester concentrations.

**Product Studies.** The gaseous products from the decomposition were collected from breakseal flasks into a calibrated vacuum line. The total gas yield was thus obtained. The composition of the gas mixture was estimated by the sensitivities of the mass spectrometer to the components of the mixture. The *t*-butyl alcohol from the decomposition of the deuterated perester in aqueous dioxane was separated by glpc using a 30 ft × 1/8 in. column packed with 30% SE-30 on Chromosorb W. Its mass spectrum was identical with that of authentic *t*-butyl alcohol.

**Acknowledgment.** This work was supported by a grant from the Army Research Office, Durham. We are indebted to Dr. C. E. Klopfenstein whose computer program for molecular orbital calculations was modified to include heteroatom and overlap parameters and who assisted us in adapting the Hoffman program to the IBM 360 computer system. We are also grateful to Professor M. Schurr and Professor W. T. Simpson for many penetrating criticisms of this work and to Professor M. Sage for helpful discussions.

## The Coupling Reactions of 1-Chlorocyclopentene, 1-Chlorocyclohexene, and 1-Chlorocycloheptene with Phenyllithium. The Question of Cycloallenic Intermediates<sup>1</sup>

Lawrence K. Montgomery and Lynn E. Applegate<sup>2</sup>

Contribution No. 1430 from the Department of Chemistry, Indiana University, Bloomington, Indiana 47401. Received February 8, 1967

**Abstract:** In previous work it was postulated that the coupling reactions of 1-chlorocyclopentene and 1-chlorocyclohexene with phenyllithium in ether at 150°, which yield 1-phenylcyclopentene and 1-phenylcyclohexene, proceed *via* an elimination-addition mechanism involving short-lived cycloalkyne intermediates. An alternative mechanism utilizing cycloallenic intermediates was not rigorously ruled out, however. In the present study the reactions of 1-chloro-2-methylcyclopentene, 2-chloro-3-methylcyclopentene, 1-chloro-2-methylcyclohexene, 2-chloro-3-methylcyclohexene, 1-chlorocyclopentene-2,5,5-*d*<sub>3</sub>, 1-chlorocyclohexene-2,6,6-*d*<sub>3</sub>, 1-chlorocycloheptene, and 1-chlorocycloheptene-2,7,7-*d*<sub>3</sub> with phenyllithium have been examined. In addition, isotopic rate constant ratios, *k*<sub>H</sub>/*k*<sub>D</sub>, were obtained from competition experiments employing 1-chlorocycloalkenes and 1-chlorocycloalkenes-2,*n*,*n*-*d*<sub>3</sub> (*n*-membered ring). Rate constant ratios for the five-, six-, and seven-membered rings were 3.36 ± 0.40, 5.34 ± 0.40, and 7.16 ± 0.40, respectively. The results of these studies provide compelling evidence that the coupling reactions of 1-chlorocyclopentene, 1-chlorocyclohexene, and 1-chlorocycloheptene with phenyllithium take place predominantly, if not exclusively, by way of an elimination-addition mechanism involving cycloalkyne intermediates.

In 1944, Wittig and Harborth<sup>3</sup> reported that 1-phenylcyclohexene was formed in 5% yield upon heating 1-chlorocyclohexene and phenyllithium in ether at 100°. Later, it was suggested<sup>4</sup> that this reaction might, in a

manner analogous to the coupling reactions of aryl halides with aryllithium reagents,<sup>5</sup> proceed *via* an elimination-addition mechanism involving a cyclohexyne intermediate. In an effort to delineate the

mechanism of substitution, Scardiglia and Roberts<sup>4,6</sup> treated a 1:1 mixture of 1-chlorocyclohexene-6-<sup>14</sup>C (1) and 1-chlorocyclohexene-2-<sup>14</sup>C (2) with phenyllithium in ether at 150°. The 1-phenylcyclohexene which was obtained in 28% yield contained 23% (relative to the total <sup>14</sup>C content) of the <sup>14</sup>C label in the 1 position (8). The fact that <sup>14</sup>C was found in the 1 position demonstrates that at least a portion of the substitution product arose from a mechanism other than direct nucleophilic displacement; the percentage of <sup>14</sup>C in the 1 position is close to that predicted on the basis of a cyclohexyne hypothesis (Chart I).

Chart I

1-Chlorocyclopentene also reacts with phenyllithium at elevated temperatures.<sup>6,7</sup> In a tracer study of this reaction, 1-chlorocyclopentene-1-<sup>14</sup>C gave rise to 1-phenylcyclopentene in which the starting <sup>14</sup>C label was partitioned among the 1 (48.9%), 2 (36.2%), and 5 (14.9%) positions.<sup>6</sup> In the absence of competing or consecutive rearrangement reactions, the <sup>14</sup>C should have been distributed equally between the 1 and the 2 positions (10 and 11) had cyclopentyne-1-<sup>14</sup>C (9) intervened in the substitution process (Chart II). It has been proposed<sup>6</sup> that a portion of the <sup>14</sup>C in the 2 position rearranged to the 5 position by way of base-induced (phenyllithium or lithium ethoxide) allylic isomerization (10 → 14, Chart II).

Chart II

Whereas aryl halides can give only one type of 1,2-elimination product, arynes, cyclic vinyl halides can, in principle, give either a cycloalkyne or a cycloallene. The patterns of <sup>14</sup>C-isotope rearrangement discussed above fit a multistep cycloallenic substitution sequence almost as well as they do a cycloalkyne mechanism. To illustrate, 1,2-cyclopentadiene-2-<sup>14</sup>C (15) would yield organolithium intermediates 16 and 17 in a 1:1 ratio if one-half of the phenyllithium added to the

middle and one-half to the ends of the allenic system in 15 (Chart III). Intermediate 16 would ultimately produce 1-phenylcyclopentene-1-<sup>14</sup>C. Protonation of 17 followed by prototropic rearrangement would afford 12, which could continue on to 14. This mechanism cannot be criticized too severely for the necessity of hav-

Chart III

ing to rearrange the double bond of 17 into conjugation with the phenyl group (17 → 12), since the cycloallene mechanism requires similar transformations. The <sup>14</sup>C data for 1-chlorocyclohexene can also be explained in terms of a cycloallenic mechanism, provided that the ratio of middle-to-end addition is again 1:1.

Roberts and co-workers<sup>6</sup> have stated a definite preference for the cycloalkyne mechanism. Two arguments which they advanced in arriving at this preference were the following. The cycloalkyne hypothesis readily accounts for the *primary pattern* (excluding the prototropic rearrangement of 10 to 14) of <sup>14</sup>C-isotope rearrangement, for phenyllithium should add with equal probability to the two carbons of the cycloalkyne triple bonds (kinetic isotope effects and minor steric differences neglected). It is less obvious why cycloallenes should react with phenyllithium in the manner required by the <sup>14</sup>C data. A second objection to cycloallenic intermediates involves a selectivity argument. Were cycloallenic intermediates to intervene, they would have to display some measure of selectivity, for a nonstatistical addition of phenyllithium is called for by the results of the <sup>14</sup>C experiments. In view of this selectivity, it is difficult to see why phenyllithium should add to both five- and six-membered ring allenic intermediates to give essentially equal portions of middle-to-end addition. These arguments, though satisfactory from the qualitative point of view, are difficult to translate into quantitative terms. For example, how much more selective should 1,2-cyclohexadiene be than 1,2-cyclopentadiene? Since they should both be highly reactive, might not the selectivity difference be undetectable?

A number of observations in the literature bear directly or indirectly on the question of the suitability of cycloallenes as intermediates in the nucleophilic substitution reactions of nonactivated cyclic olefinic halides. In an attempted synthesis of cyclononyne, Blomquist<sup>8</sup> found that 1-chlorocyclononene reacted with alcoholic potassium hydroxide to give a mixture of cyclononyne and 1,2-cyclononadiene. Moore and Ward<sup>9</sup> have studied acetylene-allene equilibria in C<sub>9</sub>-, C<sub>10</sub>-, and C<sub>11</sub>-cyclic systems and found that the allene became progressively more stable relative to the isomeric alkynes as the ring size was decreased. A 1,2-cyclononadiene to cyclononyne equilibrium ratio of

about 13:1 (potassium *t*-butoxide, *t*-butyl alcohol, 100.3°) was obtained by these authors. Ball and Landor<sup>10</sup> observed that 1-chlorocyclononene and 1-chlorocyclodecene react with sodamide in liquid ammonia to give the corresponding allenes, contaminated with about 15% of the cyclic acetylenes. Under similar reaction conditions 1-chlorocycloheptene and 1-chlorocyclooctene yielded, at least formally, allene dimers (20 and 21). Bottini and Schear<sup>11</sup> treated

20

21

2-chloro- and 2-bromo-3-(2-hydroxyethoxy)cyclohexene (22) with potassium *t*-butoxide in dimethyl sulfoxide and obtained products 23 and 24. These authors argue effectively that 23 was formed *via* an elimination-addition sequence involving a cycloallenic intermediate and, further, that cycloalkynes were not formed at all in this system. Finally, very recently Wittig<sup>12</sup> has

24

trapped 1,2-cyclohexadiene, generated through the action of potassium *t*-butoxide on 1-bromocyclohexene in dimethyl sulfoxide, using the highly reactive diene 1,3-diphenylbenzo[*c*]furan. Taken as a whole, the above observations strongly suggest the need for additional research on the mechanism of the reactions of 1-chlorocyclohexene and 1-chlorocyclopentene with phenyllithium.

In the present investigation two experimental approaches have been employed in an attempt to unambiguously distinguish between the cycloalkyne and the cycloallene pathways. The first approach might be termed methyl-group blocking experiments. 2-Methylcycloalkanones, when treated sequentially with phosphorus pentachloride and base, yield mixtures of 1-chloro-2-methylcycloalkenes and 1-chloro-*n*-methylcycloalkenes (*n*-membered ring). The former halides cannot give rise to cycloalkynes, while the latter can. A simple mechanistic test is thus provided by examining the reactions, or lack thereof, of the two types of chlorides with phenyllithium. Moreover, the methyl groups of the 1-chloro-*n*-methylcycloalkenes serve as structural labels for the observation of any rearrangement which accompanies substitution. The methyl-group blocking experiments, though extremely classical in nature, prove to be an effective mechanistic tool, particularly in view of the relative ease with which they can be carried out experimentally. In a second approach, deuterium-labeled vinyl chlorides have been used to detect rearrangement and to probe the timing of the bond-breaking processes that lead to products.

## Results and Discussion

**General.** The olefinic chlorides required for this study were prepared from appropriate ketones by way

of a two-step sequence. In the first, a simple ketone, a cycloalkanone- $\alpha,\alpha',\alpha'-d_4$ , or a 2-methylcycloalkanone was treated with phosphorus pentachloride in methylene chloride, affording a mixture of the desired olefinic chloride(s) and the *gem*-dichloride. The crude chloride mixtures were treated with potassium *t*-butoxide in *t*-butyl alcohol, sodium methylsulfinyl carbanion in dimethyl sulfoxide, or potassium *t*-butoxide in dimethyl sulfoxide in order to dehydrohalogenate the *gem*-dichlorides. The deuterated cycloalkanones were prepared from cycloalkanones by base-catalyzed proton-deuteron exchange with deuterium oxide. Authentic samples of possible olefinic chloride-phenyllithium substitution products were synthesized following standard procedures.

The previously reported<sup>4,6,7</sup> coupling reactions of 1-chlorocyclopentene and 1-chlorocyclohexene with phenyllithium afforded 1-phenylcyclopentene and 1-phenylcyclohexene in 25–35% yields. It has been found that 1-chlorocycloheptene reacts with phenyllithium under similar reaction conditions to give 1-phenylcycloheptene; typical yields were somewhat higher. In an effort to determine whether these substitution reactions are a general reaction of olefinic chlorides, *trans*-3-chloro-2-pentene and phenyllithium were subjected to the standard reaction conditions. Analysis of the reaction products revealed that 55% of the starting chloride had been consumed, but that neither coupling products (*trans*- and *cis*-2-phenyl-2-pentene, *trans*- and *cis*-3-phenyl-2-pentene, 2-phenyl-1-pentene) nor acetylenic elimination products (1- and 2-pentyne) were present. These findings could be rationalized in a variety of ways; an extended discussion of such possibilities would seem of doubtful value. *cis*-3-Chloro-2-pentene would be a better model for the cyclic chlorides, and it is possible that an examination of its reaction with phenyllithium might be more revealing. Considering the equivocity of the *trans* isomer results, however, additional effort was not expended on this aspect of the coupling reactions.

**The C<sub>5</sub> Ring System.** An ether solution which was 0.072 *M* in 1-chloro-2-methylcyclopentene and 0.76 *M* in phenyllithium was sealed in a stainless steel bomb and heated at 150° for 1.3 hr.<sup>13</sup> The cooled reaction mixture was poured into water; the resulting organic reaction products were separated and quantitatively analyzed. A summary of products of interest is reported in Table I. Little or no (2% or less) coupled products were observed, indicating that an olefinic proton is required to achieve substitution.

Only 39% of the initial 1-chloro-2-methylcyclopentene was recovered. Independent of what the process or processes were that destroyed the starting material, it is interesting to note that a minimum<sup>14</sup> of 40% of the chlorine in the starting olefin ended up as chloride ion in the aqueous wash solutions. About 21% of the chlorine in the initial 1-chloro-2-methylcyclopentene was not accounted for. Presumably nonvolatile, chlorine-containing products, perhaps polymer, were also formed.

(13) All of the coupling reactions in this study were conducted at (150 ± 10)° for a period of 1.3 hr. The concentrations of the reactants varied somewhat from experiment to experiment.

(14) A large quantity of bromide ion which came from the phenyllithium preparation was also present, making a precise chloride ion analysis difficult. Control experiments indicated that the chloride analyses reported here are low by several per cent (8–12% of the total chloride ion).

<sup>a</sup> Conducted in 100 ml of anhydrous ether at  $(150 \pm 10)^\circ$  for 1.3 hr. <sup>b</sup> No analysis was made. Presumed to be absent. <sup>c</sup> Trace of unidentified component(s).

One final product of interest was the trace amount of 1-methylcyclopentene. Since it was not in the 1-chloro-2-methylcyclopentene, it most likely arose by way of metal-halogen interconversion.

When 2-chloro-3-methylcyclopentene was heated with phenyllithium, 85% reaction occurred (Table II).

**Table II.** Reaction of 2-Chloro-3-methylcyclopentene with Phenyllithium

<sup>a</sup> Conducted in 140 ml of ether at  $(150 \pm 10)^\circ$  for 1.3 hr. <sup>b</sup> No analysis was made. Presumed to be absent.

Two substitution products were detected and isolated employing glpc. One was unequivocally identified as 3-methyl-2-phenylcyclopentene. The chromatographic retention time behavior of the other product was identical with that of a nonseparable mixture of 3-methyl-1-phenylcyclopentene and 4-methyl-1-phenylcyclopentene, which was prepared independently starting from 3-methylcyclopentanone. Moreover, the nmr and infrared spectra of the second substitution product were similar, though not identical, with those of the olefin mixture. One noteworthy spectral difference was that the nmr vinyl proton absorption of the coupled product was a crude doublet, while the same absorption region of the olefin mixture was broader and more complex. It would not be unreasonable to infer from this that the substitution product was predominantly one isomer, 3-methyl-1-phenylcyclopentene, the product that would be expected ( $25 \rightarrow 26 \rightarrow 27 + 28$ ) for an elimination-addition substitution mechanism involving a 3-methylcyclopentene intermediate **26**. The fact that 3-methyl-

2-phenylcyclopentene and 3-methyl-1-phenylcyclopentene were obtained in roughly equal quantities (Table II) lends additional support to the postulated intermediacy of 3-methylcyclopentene. Slight steric

differences in the transition states for the formation of organolithium intermediates **27** and **28** are probably responsible for the slight preferential formation of 3-methyl-1-phenylcyclopentene.

One aspect of the 2-chloro-3-methylcyclopentene study that is somewhat disturbing is that no allylic isomerization of the substitution products was noted. Although limited isomerization of 3-methyl-1-phenylcyclopentene to 4-methyl-1-phenylcyclopentene would not have been discerned, prototropic rearrangement of 3-methyl-2-phenylcyclopentene to 2-methyl-1-phenylcyclopentene would have been easily detected by glpc. It could be argued that base-catalyzed allylic isomerization of 3-methyl-2-phenylcyclopentene is slow owing to the fact that proton removal must occur at a tertiary carbon; such a rationalization is not entirely satisfying. Accordingly, the mechanism of coupling was probed by a second method.

The reaction of 1-chlorocyclopentene-2,5,5-*d*<sub>3</sub> with phenyllithium provided coupled product in only 11% yield, suggesting that a kinetic isotope effect was operative. About 65% of the starting chloride was recovered. The infrared and nmr spectra of the recovered olefin were identical with those of the starting material. Proton nmr analysis of the substitution product indicated that  $0.14 \pm 0.03$  deuterons and  $1.84 \pm 0.20$  deuterons resided in olefinic and saturated ring positions, respectively. In order to gain an indication as to how much of the coupled product existed as some form of an organolithium species at the end of the reaction, 1-chlorocyclopentene was treated with phenyllithium, and the resultant products were treated with deuterium oxide. An average of  $0.20 \pm 0.03$  deuterium was incorporated into the olefinic position; a maximum of 0.2 deuterium was present in the saturated positions. Mass spectral analysis of the benzene-benzene-*d*<sub>1</sub> showed that about 12% of the initial phenyllithium survived the reaction. In Table III the experimental

<sup>a</sup> Conducted in ether at  $(150 \pm 10)^\circ$  for 1.3 hr. <sup>b</sup> Average number of deuterons per position per molecule. <sup>c</sup> Student's distribution, 99.5% confidence limit.

deuterium distribution in the 1-chlorocyclopentene-2,5,5-*d*<sub>3</sub> coupled product is compared to calculated distributions based on four alternative mechanistic hypotheses: cyclopentene-3,3-*d*<sub>2</sub> intermediate, no allylic isomerization; cyclopentene-3,3-*d*<sub>2</sub> intermediate, allylic isomerization as required by the <sup>14</sup>C-tracer study;<sup>6</sup> 1,2-cyclopentadiene-1,3-*d*<sub>2</sub> intermediate, sufficient isomerization to obtain 1-phenylcyclopentene (*vide supra*); 1,2-cyclopentadiene-1,3-*d*<sub>2</sub> intermediate, allylic isomer-

ization as required by the  $^{14}\text{C}$ -tracer study.<sup>6</sup> Clearly, the cyclopentyne-3,3- $d_2$  isomerization hypothesis provides the best fit to the data. The glaring inability of the 1,2-cyclopentadiene-1,3- $d_2$  hypotheses to accommodate the data is also significant.

The kinetic isotope effect was examined in a competition experiment employing 1-chlorocyclopentene and 1-chlorocyclopentene-2,5,5- $d_3$  in a 2.7:1 molar ratio. So little deuterium was present in the coupled product that an isotope effect on coupling could not be reliably determined directly from product composition. The unreacted chlorides could be accurately assayed, however. From the initial and final quantities of 1-chlorocyclopentene and 1-chlorocyclopentene-2,5,5- $d_3$ , a rate constant ratio,  $k_{\text{H}}/k_{\text{D}}$ , for the disappearance of starting material of  $3.36 \pm 0.40$  was calculated using the standard formula.<sup>15</sup> In applying this formula, the usual assumptions<sup>16</sup> were made, namely that the rate expressions for the two competing reactions were first order in substrate but otherwise differed only in the values of the specific rate constants  $k_{\text{H}}$  and  $k_{\text{D}}$ .

The value of  $k_{\text{H}}/k_{\text{D}}$  is quite large, considering the temperature at which the competition experiment was conducted. If merely the zero-point energies of the CH and CD stretching vibrations were lost in going to the coupling reaction transition states, the maximum expected rate constant ratio at  $150^\circ$  would be about 3.8<sup>16,17</sup>. Even if  $k_{\text{H}}/k_{\text{D}}$  for substitution was lower than the measured ratio, it is obvious that it was sizeable in view of the modicum of deuterium that was incorporated into the product. Consequently, the competition experiment provides valuable evidence in support of the proposed elimination-addition mechanism. The magnitude of the isotope effect and the fact that 1-chlorocyclopentene-2,5,5- $d_3$  was recovered unmodified make it clear that the rate-determining step in substitution is an irreversible metallation at the olefinic proton (deuteron) position or, alternatively, concerted elimination to cyclopentyne (cyclopentyne-3,3- $d_2$ ).

**The  $\text{C}_6$  Ring System.** Preparative glpc could not be conveniently employed to separate 1-chloro-2-methylcyclohexene and 2-chloro-3-methylcyclohexene. A mixture of the two isomers was treated with phenyllithium. In Table IV a summary of reactants and products is displayed. The product distribution

(17) Calculation based on CH and CD stretching frequencies (infrared data) of 3077 and 2294  $\text{cm}^{-1}$ .

appears to be very much the same as with the methyl-labeled chlorocyclohexenes. About 38% of the 1-chloro-2-methylcyclohexene reacted. No 2-methyl-1-phenylcyclohexene was observed, implying that substitution products were not formed from 1-chloro-2-methylcyclohexene. If the coupling of 2-chloro-3-methylcyclohexene with phenyllithium followed a route involving 3-methylcyclohexyne, 3-methyl-2-phenylcyclohexene and 3-methyl-1-phenylcyclohexene should have been produced in a 1:1 ratio. A ratio close to this value was observed experimentally. As was the case with the products from 2-chloro-3-methylcyclopentene, the 1-phenyl isomer was favored slightly.

1-Chlorocyclohexene-2,6,6- $d_3$  and phenyllithium gave a deuterium-labeled substitution product in 13% yield. Unreacted olefinic chloride was recovered and was found to be unchanged. Analysis of the deuterium distribution in the coupled product showed, as anticipated, that an average of  $1.93 \pm 0.11$  deuterons was located in the saturated ring positions. Quite unexpected, however, was the finding that  $0.82 \pm 0.09$  deuteron resided in the olefinic position. Mass spectral analysis of the benzene from the reaction revealed that only 7.0 mmols of benzene- $d_1$  was formed. About 20.2 mmols of 1-chlorocyclohexene-2,6,6- $d_3$  reacted. A plausible explanation of these results would be that a large primary kinetic isotope effect retarded the rate of the elimination-addition pathway to such an extent that direct nucleophilic substitution could effectively compete for the 1-chlorocyclohexene-2,6,6- $d_3$ . Isotope rate constant measurements indicate that this is not the case.

The kinetic isotope effect in the  $\text{C}_6$  system was explored utilizing the competition method. A 3:1 mixture of 1-chlorocyclohexene and 1-chlorocyclohexene-2,6,6- $d_3$  afforded a substitution product possessing nmr and infrared spectra which were virtually indistinguishable from nondeuterated 1-phenylcyclohexene. A  $k_{\text{H}}/k_{\text{D}}$  of  $5.34 \pm 0.40$  was calculated, based on the consumption of olefinic chlorides. It is clear from these observations that 1-chlorocyclohexene-2,6,6- $d_3$  does not react with phenyllithium by way of direct nucleophilic displacement. About the only way to bring the 1-chlorocyclohexene-2,6,6- $d_3$  product study and the  $k_{\text{H}}/k_{\text{D}}$  measurement into compatibility is to assume that coupling takes place *via* a cyclohexyne-3,3- $d_2$  (32) intermediate and that the organolithium compounds which result from phenyllithium addition (29) react preferentially with the substrate ( $29 + 30 \rightarrow 31 + 32$ ). If the reaction is autocatalytic,  $k_{\text{H}}/k_{\text{D}}$  cannot

be calculated in the usual manner.<sup>18</sup> Nevertheless, qualitatively it is clear that a large isotope effect operates on the coupling reaction.

**The  $\text{C}_7$  Ring System.** Methyl-group blocking experiments were not carried out on a  $\text{C}_7$  system. In order to see if substitution occurs with cycloheptyl chlorides, 1-chlorocycloheptene-2,7,7- $d_3$  was heated with phenyllithium under the standard reaction con-

ons. Substitution product was obtained in 15% d, which is somewhat higher than with the C<sub>5</sub> and deuterated chlorides. Proton nmr analysis of the plated product indicated the presence of  $0.17 \pm 0.02$  deuteron per molecule in the olefinic position and  $5 \pm 0.12$  deuterons per molecule in the saturated positions. Since the saturated proton region of the spectrum of 1-phenylcycloheptene consisted of a complex absorption extending continuously from 1.1 to 2.9 ppm downfield from tetramethylsilane, it was possible<sup>18</sup> to determine the position(s) of the two deuterons on the cycloheptene ring. The deuteron spectrum of the substitution product,<sup>19</sup> however, revealed two types of aliphatic deuterons, centered at 1.0 and 2.50 ppm. The areas of the deuteron absorption peaks were approximately equal, the downfield peak being slightly the larger. These data provide excellent evidence that substitution takes place by way of cycloheptyne-3,3-*d*<sub>2</sub> (33) intermediate.

the  $k_H/k_D$  for competition between 1-chlorocyclopentene and 1-chlorocycloheptene-2,7,7-*d*<sub>3</sub> was 7.16  $\pm$  0.40. As in the C<sub>5</sub> and C<sub>6</sub> systems, the product retained little deuterium. At least two factors might reasonably be responsible for the unusually large magnitude of the rate constant ratio. First, it has been reported that tunneling is important in certain bimolecular elimination reactions and that  $k_H/k_D$  is increased accordingly.<sup>20</sup> Second, a variety of detailed elimination mechanisms can be envisioned which involve multicenter transition states. With such mechanisms the CH and CD stretching and bending frequencies might both be important in determining the magnitude of the isotope effect.<sup>21</sup>

**The Question of Cycloallenic Intermediates.** The experimental results presented in this paper in conjunction with the earlier <sup>14</sup>C-tracer studies<sup>6</sup> demonstrate beyond reasonable doubt that the coupling reactions of 1-chlorocyclopentene, 1-chlorocyclohexene, and 1-chlorocycloheptene with phenyllithium proceed predominantly, if not exclusively, by way of elimination-addition mechanisms involving cycloalkyne intermediates. It is clear, nonetheless, that the olefinic chlorides enter into reactions other than substitution. For example, in no case was there a 1:1 molar correspondence between chloride consumed and coupled product formed. 1-chloro-2-methylcyclopentene and 1-chloro-2-methylcyclohexene underwent significant reaction, despite the fact that they possessed no olefinic protons. It is difficult to say whether or not cycloallenic intermediates might be involved in these side reactions.

Returning to the findings of Wittig,<sup>12</sup> Bottini,<sup>11</sup> and Landor,<sup>10</sup> it appears that 1-halocycloalkenes and strongly basic nucleophiles can give rise to either cyclo-

alkynes or cycloallenes, depending upon the particular halide, base, and reaction conditions employed. Factors such as the relative rates of cycloalkyne and cycloallene formation, the rate of cycloalkyne-cycloallene interconversion, and cycloalkyne-cycloallene relative stability are probably important in determining which reaction path is followed in a given system. Unfortunately, little is known concerning the above factors. In preliminary results<sup>22</sup> from a study of the quantitative conformational analyses of C<sub>8</sub>, C<sub>9</sub>, and C<sub>10</sub> cycloalkynes and cycloallenes (extended Wiberg<sup>23</sup> scheme), we have found that the energies of the conformations of minimum energy in these systems are complex composites of bond angle, torsional, and nonbonded energy terms. Accordingly, it is doubtful that the cycloalkyne-cycloallene equilibrium data of Moore and Ward<sup>9</sup> provide reliable insight into the relative stabilities of cycloalkynes and cycloallenes in smaller ring systems. One interesting point that has been noted concerns the general difficulty of placing a triple bond in the lower members of the medium-sized rings. For simple geometrical reasons alone, the collinear, four-atom grouping of a strain-free triple bond cannot be placed in a carbocyclic ring containing less than nine carbon atoms without introducing substantial bond angle distortions at one or more positions. Conformational analysis of the C<sub>8</sub>-C<sub>10</sub> cycloalkynes have made it evident that the restrictions that the linear four-atom acetylenic array impose on a cyclic system are not as severe as might be expected on the basis of geometrical considerations. This is true owing to the fact that C—C≡C bond angles are relatively easy to distort; the bending force constants for C—C≡C bond angles are about one-third those for C—C—C bond angles.<sup>24</sup> It is not clear how important a role these force constant differences might play in determining conformational preferences and relative cycloalkyne stabilities in the smallest cycloalkynes, for it is known that highly strained systems cannot be satisfactorily treated using the usual quantitative conformational analysis schemes.

## Experimental Section

Boiling points are uncorrected. Nmr and infrared spectra were routinely recorded and are assumed to be in satisfactory agreement with authentic or predicted spectra when they are not explicitly discussed. The nmr spectra were obtained from dilute chloroform-*d*<sub>1</sub> solutions using a Varian Associates A-60 spectrometer. Chemical shifts are reported as parts per million displacements from tetramethylsilane as an internal standard. Infrared spectra were generally recorded on both Perkin-Elmer Model 137 and Model 137-G (near-infrared) Infracord spectrometers. Quantitative glpc determinations were carried out on an F & M Scientific Model 609 flame-ionization gas chromatograph equipped with a Minneapolis-Honeywell recorder (Model Y153-999) fitted with a Disc Instruments integrator. All of the columns used with the F & M instrument were stainless steel and 8 ft in length (0.25 in. o.d.). The columns and their designations are: 20% silicone gum GE XE-60 on 60-80 mesh Chromosorb P (XEA); 20% Carbowax 20M on 60-80 mesh Chromosorb P (20CWA); 10% Carbowax 20M on 60-80 mesh Diatoport S (10CWA). Preparative glpc was conducted on a F & M Model 720 gas chromatograph fitted with 8-ft (0.375-in. o.d.) stainless steel columns. The columns were: 20% silicone gum GE XE-60 on 60-80 mesh Chromosorb P (XEP); 20% Carbowax 20M on 60-80 mesh Chromosorb P (CWP). Mass

spectra were recorded on a Consolidated Electrodynamics Corp Model 21-260 mass spectrometer.

**Cyclohexanone-2,2,6,6- $d_4$ .** A solution consisting of 45 g (0.46 mole) of cyclohexanone, 80 g (4.00 moles) of deuterium oxide (99.8%), 10 ml of triethylamine, and 400 ml of anhydrous dioxane was refluxed for 48 hr. Deuterium oxide, water, triethylamine, and dioxane were removed by distillation. The exchange was repeated four more times. Final distillation afforded 27.1 g (58%) of cyclohexanone-2,2,6,6- $d_4$ , bp 148–153°.

**Cyclopentanone-2,2,5,5- $d_4$**  was prepared by Mr. D. Armstrong in the laboratories of V. J. Shiner, Jr., following a procedure similar to the one outlined above for cyclohexanone-2,2,6,6- $d_4$ . We wish to thank Professor Shiner for lending us this material.

**Olefinic Chlorides.** The preparation of 1-chloro-2-methylcyclopentene and 2-chloro-3-methylcyclopentene illustrates the general procedure which was employed for the preparation of olefinic chlorides from ketones. A solution of 39.2 g (0.40 mole) of 2-methylcyclopentanone in 45 ml of methylene chloride was added slowly to 103 g (0.50 mole) of phosphorus pentachloride in 530 ml of methylene chloride (4–5°). The solution was stirred for 1 hr at this temperature, allowed to warm to 18° over a 1-hr period, and poured onto crushed ice. The methylene chloride layer was separated and washed thoroughly with 40% sodium hydroxide solution and water. Removal of the solvent by distillation left a 26.4-g mixture of 1-chloro-2-methylcyclopentene, 2-chloro-3-methylcyclopentene, and 1,1-dichloro-2-methylcyclopentane. The latter compound was dehydrohalogenated following method 1.

**Dehydrohalogenation Method 1.** The crude chloride mixture was added dropwise over a 5-min period to a 0.34 *M* solution of methylsulfinyl carbanion (4.0 g of sodium hydride) in dimethyl sulfoxide (500 ml). The rate of addition was such that the temperature stayed within the range 18–32°. The solution was stirred an additional 5 min at 24° and poured into water. The reaction products were taken up in methylene chloride; the extract was washed thoroughly with water. Distillation afforded 8.36 g (18% based on ketone) of 1-chloro-2-methyl- and 2-chloro-3-methylcyclopentene (45:55), bp 120–123°. The two chlorides were separated employing preparative glpc (XEP, 125°, 200 cc/min).

In general the olefinic chlorides were purified by preparative glpc, stored in sealed ampoules under refrigeration, and redistilled immediately prior to use. Typical purity after distillation as assessed by glpc was 99% or greater.

**1-Chloro-2-methylcyclohexene and 2-Chloro-3-methylcyclohexene.** 2-Methylcyclohexanone (44.0 g, 0.397 mole), phosphorus pentachloride (103 g, 0.49 mole), and sodium methylsulfinyl carbanion (method 1; 7.2 g, 0.30 mole of sodium hydride in 300 ml of dimethyl sulfoxide) provided 7.3 g (14%; 99% purity by glpc; 20 CWA, 100°, 33 cc/min) of the two olefinic chlorides, bp 58–63° (23 mm) [lit.<sup>25</sup> bp 41–42° (8 mm)]. A 65:35 mixture of isomers was indicated by glpc. A 65:35 mixture was also inferred from nmr. The predominant isomer was 1-chloro-2-methylcyclohexene.

**1-Chlorocyclopentene.** Cyclopentanone (44.0 g, 0.52 mole), phosphorus pentachloride (135 g, 0.65 mole), and potassium *t*-butoxide (method 2; 12.4 g, 0.32 equiv of potassium in 400 ml of *t*-butyl alcohol) provided 16.3 g of crude 1-chlorocyclopentene, bp 99–108°, 93% purity by glpc (29%). Chromatographed material (CWP, 120°, 150 cc/min) was redistilled, bp 102–103° [lit.<sup>6</sup> bp 102–103°].

**1-Chlorocyclohexene.** Cyclohexanone (19.6 g, 0.200 mole), phosphorus pentachloride (49.5 g, 0.238 mole), and potassium *t*-butoxide (method 2; 6.2 g, 0.159 equiv of potassium in 200 ml of *t*-butyl alcohol) provided 7.9 g of crude 1-chlorocyclohexene, bp 139–141°, 95% purity by glpc (33%). Chromatographed material (CWP, 145°, 150 cc/min) was redistilled, bp 140–141° [lit.<sup>26</sup> bp 142–143°].

**1-Chlorocycloheptene.** Cycloheptanone (44.8 g, 0.400 mole) and phosphorus pentachloride (104 g, 0.500 mole) gave 41.9 g of crude chlorides which was treated with base following method 3.

**Dehydrohalogenation method 3** was very similar to method 1, the principal difference being that potassium *t*-butoxide (MSA Research Corp.) was employed as the base. The chlorides from cycloheptanone were added to a solution of 15 g of potassium *t*-butoxide in 190 ml of dimethyl sulfoxide. About 17 g (80% 1-chlorocycloheptene; 24%) of dehydrohalogenation products, bp 150–176°, were obtained. The chromatographed material (CWP, 140°, 150 cc/min) was redistilled, bp 55.0–55.5° (12 mm) [lit.<sup>10</sup> bp 54–58° (14 mm)].

**1-Chlorocyclopentene-2,5,5- $d_4$ .** Cyclopentanone-2,2,5,5- $d_4$  (45.5 g, 0.517 mole), phosphorus pentachloride (135 g, 0.649 mole), and potassium *t*-butoxide (method 2; 45 g, 1.15 equiv of potassium in 875 ml of *t*-butyl alcohol) provided 17.9 g of olefinic chloride (93% purity; 31%), bp 103–105°. Chromatographed (CWP, 120°, 150 cc/min) and redistilled, bp 103–104°, 1-chlorocyclopentene-2,5,5- $d_4$ ,  $n_D^{25}$  1.4379, contained  $3.00 \pm 0.06$  deuterons/molecule, as assessed by proton nmr (benzene, quantitative internal standard). There was no visually discernible absorption in the olefinic proton region.

**1-Chlorocyclohexene-2,6,6- $d_4$ .** Cyclohexanone-2,2,6,6- $d_4$  (26.6 g, 0.261 mole), phosphorus pentachloride (70.7 g, 0.340 mole), and potassium *t*-butoxide (method 2; 10 g, 0.26 equiv of potassium in 350 ml of *t*-butyl alcohol) provided 23.8 g of olefinic chloride (62% purity; 46%), bp 139–151°. Chromatographed (CWP, 145°, 150 cc/min) and redistilled, bp 139–141°, 1-chlorocyclohexene-2,6,6- $d_4$ ,  $n_D^{25}$  1.4797, contained  $3.00 \pm 0.06$  deuterons/molecule, as assessed by proton nmr (biphenyl, quantitative internal standard). There was no visually discernible absorption in the olefinic proton region.

**1-Chlorocycloheptene-2,7,7- $d_4$**  was available from another study.<sup>10</sup> Chromatographed (CWP, 140°, 150 cc/min) and redistilled, bp 52–53° (11 mm), 1-chlorocycloheptene-2,7,7- $d_4$ ,  $n_D^{25}$  1.4859, contained  $2.89 \pm 0.06$  deuterons/molecule, as assessed by proton nmr (biphenyl, quantitative internal standard). There was no visually discernible absorption in the olefinic proton region.

***trans*-3-Chloro-2-pentene.** 3-Pentanone (137.6 g, 1.60 moles) and phosphorus pentachloride (416 g, 2.00 mole) gave about 100 g of a mixture of *trans*- and *cis*-3-chloro-2-pentene and 3,3-dichloropentane. The *trans* isomer, bp 92–93° [lit.<sup>27</sup> bp 92–93°], could be easily obtained in high purity by fractional distillation and was used in the attempted coupling experiment.

**Phenyllithium Coupling Reactions.** The reactions of 1-chloro-2-methylcyclohexene and 2-chloro-3-methylcyclohexene with phenyllithium illustrate the general procedure. A solution consisting of 3.692 g (0.0284 mole) of 1-chloro-2-methylcyclohexene, 2.308 g (0.0177 mole) of 2-chloro-3-methylcyclohexene, and 0.221 mole of phenyllithium<sup>28</sup> in 210 ml of ether was placed in a 300-ml stainless steel bomb, sealed, and heated at 150  $\pm$  10° for 1.3 hr. The bomb was cooled in air (20 min), ice water (25 min), and Dry Ice-acetone (10 min), vented, and allowed to warm to room temperature. The reaction products were washed out of the bomb with water and ether. The ether layer was separated, washed with two 100-ml portions of water, and dried twice over 7-g quantities of anhydrous calcium chloride. Most of the ether was removed by distillation, and the reaction products were analyzed by glpc. Cyclohexanone was employed as an internal standard for low-boiling components (20 CWA, 100°, 33 cc/min) and *N,N*-dimethylaniline for high-boiling components (20 CWA, 225°, 30 cc/min). Detector response conversion factors were determined for most compounds. The responses of 1-chloro-2-methylcyclohexene and 2-chloro-3-methylcyclohexene were assumed to be equal. A mixture of 3-methyl-1-phenylcyclohexene and 4-methyl-2-phenylcyclohexene (*vide infra*) was used to estimate the conversion factor for 3-methyl-1-phenylcyclohexene. A summary of the analyses for key reaction products is provided in Table IV. Benzene, ethylbenzene, and biphenyl were also present. The substitution products were isolated employing glpc (XEP, 205°, 200 cc/min). 3-Methyl-2-phenylcyclohexene was identified by comparing its nmr and infrared spectra with those of an authentic sample. The second product, judged to be 3-methyl-1-phenylcyclohexene, possessed characteristic infrared absorption bands at 1639, 1597, and 1572  $\text{cm}^{-1}$  (*vide infra*). The nmr spectrum consisted of complex absorption (5.0 protons, assigned) from 7.5 to 6.8, complex absorption (0.83 proton) from 6.00 to 5.92, and complex absorption (10.3 protons) from 2.6 to 0.8 which included a well-defined doublet (6.5 cps) at 1.04 (*vide infra*). The chloride analysis in Table IV was carried out following a procedure outlined by Kolthoff and Stenger.<sup>29</sup>

**1-Chloro-2-methylcyclopentene and Phenyllithium.** 1-Chloro-2-methylcyclopentene (0.8382 g, 0.00723 mole) and 100 ml of 0.76 *M*

thium (0.076 mole) in ether was heated at  $150 \pm 10^\circ$  for a summary of the reaction products is provided in Table I. **trans-3-methylcyclopentene and Phenyllithium.** 2-Chloro-3-cyclopentene (1.8476 g, 0.01593 mole) and 140 ml of 1.19 M thium (0.167 mole) in ether were heated at  $150 \pm 10^\circ$  for a summary of the reaction products is provided in Table II A,  $70^\circ$ ,  $200^\circ$ , 35 cc/min). The substitution products were by glpc (XEP,  $125^\circ$ , 200 cc/min). The product identified as 1-phenylcyclopentene possessed characteristic infrared on bands at 1618, 1597, and  $1571\text{ cm}^{-1}$  (*vide infra*). The spectrum consisted of complex absorption (5.0 protons, as from 7.5 to 6.9, complex absorption (0.85 proton) from 6.10 complex absorption (8.15 protons) from 6.10 to 5.93, and absorption (8.15 protons) from 2.9 to 1.5, which included a (7 cps) at 1.07 (*vide infra*). The product identified as 3-phenylcyclopentene possessed characteristic infrared bands at 1623, 1597, and  $1572\text{ cm}^{-1}$  (*vide infra*). The spectrum consisted of complex absorption (5.0 protons, as from 7.5–6.9, a crude doublet ( $\sim 2$  cps, 0.7 proton) at 6.07, complex absorption at 3.2–1.3 (8.2 protons), and a doublet (7 cps, 2.2 at 1.08 (*vide infra*)).

**1-Chlorocyclopentene-2,5,5- $d_3$  and Phenyllithium.** 1-Chlorocyclopentene-2,5,5- $d_3$  (9.0048 g, 0.8538 mole) and 210 ml of 0.98 M phenyllithium (0.203 mole) in ether were heated at  $150 \pm 10^\circ$  for 1.3 hr. The reaction mixture containing 5.88 g (65.3%; 20 CWA,  $70^\circ$ , 35 of 1-chlorocyclopentene-2,5,5- $d_3$  and 1.31 g (10.7%; 20  $25^\circ$ , 35 cc/min) of deuterated 1-phenylcyclopentene. Both products were isolated utilizing preparative glpc. The nmr and spectra of the recovered chloride were virtually identical to those of the starting material. Proton nmr analysis of the deuterated 1-phenylcyclopentene indicated the presence of  $0.14 \pm 0.02$  deuterons and  $1.84 \pm 0.20$  deuterons in the olefinic and saturated positions, respectively. The phenyl protons were used as an internal standard for the analysis.

The error was calculated from six integrations using a distribution analysis and employing a 99.5% confidence

**1-Chlorocyclopentene and Phenyllithium. Deuterium Oxide.** 1-Chlorocyclopentene (8.179 g, 0.0798 mole) and 0.85 M phenyllithium (0.204 mole) in ether were heated at  $150^\circ$  for 1.3 hr. Exactly 50.0 ml of deuterium oxide was added after the reaction products. The products were then processed in the manner. The reaction products included 3.04 g (37.5%;  $70^\circ$ , 35 cc/min) of 1-chlorocyclopentene and 2.76 g (23.7%;  $110^\circ$ , 35 cc/min) of 1-phenylcyclopentene. Analysis by glpc (glpc, mass spectrometry) indicated that 12.4% of the starting phenyllithium was present at the end of the reaction. nmr analysis of glpc-collected coupled product indicated the presence of  $0.20 \pm 0.03$  deuterium and no greater than 0.2 in the olefinic and saturated ring positions, respectively.

**1-Chlorocyclopentene-2,7,7- $d_3$  and Phenyllithium.** 1-Chlorocyclopentene-2,7,7- $d_3$  (5.1308 g, 0.0384 mole) and 110 ml of 1.03 M phenyllithium (0.113 mole) in ether were heated at  $150 \pm 10^\circ$  for 1.3 hr. The reaction products included 1.83 g (35.8%; 20 CWA,  $70^\circ$ , 35 cc/min) of 1-chlorocyclopentene-2,7,7- $d_3$  and 0.97 g (20 CWA,  $170^\circ$ , 35 cc/min) of deuterated 1-phenylcyclopentene.

Both compounds were isolated utilizing preparative glpc. The nmr and infrared spectra of the recovered chloride were identical with those of the starting material. Proton nmr analysis of the deuterated 1-phenylcyclopentene indicated the presence of  $0.17 \pm 0.02$  deuterium and  $1.96 \pm 0.12$  deuterons in the olefinic and saturated ring positions, respectively.

**trans-3-Chloro-2-pentene and Phenyllithium.** *trans*-3-Chloro-2-pentene (5.0482 g, 0.04828 mole) and 125 ml of 1.24 M phenyllithium (0.113 mole) in ether were heated at  $150 \pm 10^\circ$  for 1.3 hr. Approximately one-half (2.25 g, 44.8%) of the starting chloride was unreacted (10 CWA,  $70^\circ$ , 30 cc/min). Neither *trans*- nor *cis*-3-phenyl-2-pentene, *trans*- nor *cis*-2-phenyl-1-pentene, nor acetylenic elimination products (1- and 2-pentyne) were observed (10 CWA,  $70^\circ$ , 30 cc/min).

**1-Chlorocyclopentene-2,5,5- $d_3$  and Phenyllithium.** A solution consisting of 6.0738 g (0.05926 mole) of 1-chlorocyclopentene-2,5,5- $d_3$  (2.3089 g (0.02188 mole) of 1-chlorocyclopentene-5- $d_3$  and 220 ml of 0.94 M phenyllithium (0.206 mole) in ether was heated at  $150 \pm 10^\circ$  for 1.3 hr. Analysis of the products by glpc (20 CWA,  $70^\circ$ ,  $225^\circ$ , 35 cc/min) showed that 2.97 g (35.3%) of 1-phenylcyclopentene and 2.47 g (21.2%) of substitution product were present. The chlorides were collected by glpc. Nmr analysis (biphenyl internal quantitative standard) indicated

that 0.01428 mole of each reactant survived reaction. From this result a kinetic isotope effect,  $k_H/k_D$ , of  $3.36 \pm 0.40$  was calculated<sup>15</sup> assuming simple competition. The nmr and infrared spectra of the substitution product were very similar to those for 1-phenylcyclopentene.

**1-Chlorocyclohexene, 1-Chlorocyclohexene-2,6,6- $d_3$ , and Phenyllithium.** A solution consisting of 6.0233 g (0.05162 mole) of 1-chlorocyclohexene, 2.0236 g (0.01691 mole) of 1-chlorocyclohexene-2,6,6- $d_3$ , and 180 ml of 1.00 M phenyllithium (0.180 mole) in ether was heated at  $150 \pm 10^\circ$  for 1.3 hr. Analysis of the products by glpc (XEA,  $90^\circ$ ,  $160^\circ$ , 35 cc/min) showed that 3.01 g (38.8%) of unreacted olefinic chlorides and 1.74 g (15.9%) of substitution product were present. The chlorides were collected by glpc. Nmr analysis (biphenyl internal quantitative standard) indicated that 0.01345 mole of 1-chlorocyclohexene and 0.01313 mole of 1-chlorocyclohexene-2,6,6- $d_3$  survived reaction. A  $k_H/k_D$  of  $5.34 \pm 0.40$  was calculated<sup>15</sup> from these data. The nmr and infrared spectra of the substitution product were very similar to those for 1-phenylcyclohexene.

**1-Chlorocycloheptene, 1-Chlorocycloheptene-2,7,7- $d_3$ , and Phenyllithium.** A solution consisting of 7.0284 g (0.05381 mole) of 1-chlorocycloheptene, 2.6302 g (0.01968 mole) of 1-chlorocycloheptene-2,7,7- $d_3$ , and 230 ml of 0.74 M phenyllithium (0.170 mole) in ether was heated at  $150 \pm 10^\circ$  for 1.3 hr. Analysis of the products by glpc (20 CWA,  $110^\circ$ ,  $170^\circ$ , 35 cc/min) showed that 3.26 g (29.5%) of unreacted olefinic chlorides and 2.73 g (21.4%) of substitution product were present. The chlorides were collected by glpc. Nmr analysis (biphenyl internal standard) indicated that 0.00701 mole of 1-chlorocycloheptene and 0.01468 mole of 1-chlorocycloheptene-2,7,7- $d_3$  survived reaction. A  $k_H/k_D$  of  $7.16 \pm 0.40$  was calculated<sup>15</sup> from these data. The nmr and infrared spectra of the substitution product were very similar to those for 1-phenylcycloheptene.

**Possible Olefinic Products.** A number of phenyl-substituted olefins were prepared from appropriate ketones by way of a two-step sequence. In the first, a tertiary phenylcarbinol was synthesized from the ketone (phenyllithium or phenylmagnesium bromide). The Grignard route was preferable owing to the fact that biphenyl, which was usually difficult to separate from the final product, invariably contaminated the phenyllithium preparations. When it was convenient, the phenylcarbinols were isolated and recrystallized. The second step consisted of formic acid dehydration.<sup>6</sup>

**2-Methyl-1-phenylcyclopentene and 3-methyl-2-phenylcyclopentene**<sup>10</sup> were prepared from 2-methylcyclopentanone. The two olefins could not be conveniently separated by preparative glpc and were isolated as a mixture (XEP,  $205^\circ$ , 200 cc/min). The mixture possessed important infrared absorption bands at  $\sim 1650$ ,  $\sim 1621$ , 1597, and  $1571\text{ cm}^{-1}$ . The C=C stretching bands overlapped and were difficult to assign precisely. The nmr spectrum consisted of complex absorption from 7.6 to 7.0 (5.0 protons, assigned), complex absorption from 6.07 to 5.87 (0.29 proton), complex absorption from 2.9 to 1.5 (4.94 protons) which included a multiplet associated with the methyl groups of 2-methyl-1-phenylcyclopentene at 1.80, and a doublet (7 cps, 0.089 proton) at 1.07.

**3-Methyl-1-phenylcyclopentene and 4-methyl-1-phenylcyclopentene** were prepared from 3-methylcyclopentanone. The mixture of olefins (XEP,  $205^\circ$ , 200 cc/min) possessed important infrared absorption bands at 1623, 1597, and  $1572\text{ cm}^{-1}$ . The nmr spectrum of the mixture consisted of complex absorption from 7.4 to 6.8 (5.0 protons, assigned), complex absorption from 5.95 to 5.78 (0.93 proton), complex absorption from 3.0 to 1.1 (4.9 protons), and a doublet (6.5 cps) at 1.05 (2.9 protons).

**2-Methyl-1-phenylcyclohexene and 3-methyl-2-phenylcyclohexene**<sup>11</sup> were prepared from 2-methylcyclohexanone and separated employing glpc (XEP,  $205^\circ$ , 200 ml/min).

**3-Methyl-1-phenylcyclohexene and 4-methyl-2-phenylcyclohexene**<sup>12</sup> were prepared from 3-methylcyclohexanone. The mixture of isomers possessed important infrared absorption bands at  $\sim 1645$ , 1597, and  $1645\text{ cm}^{-1}$ . The nmr spectrum of the isomers consisted of complex absorption at 7.6–6.9 (5.0 protons, assigned), complex absorption at 6.15–5.92 (1.00 proton), and complex absorption at 2.6–0.9 (10.2 protons), which included two overlapping doublets (5–7 cps) centered near 1.05.

**1-Phenylcyclopentene, 1-phenylcyclohexene, 1-phenylcycloheptene, *trans*- and *cis*-3-phenyl-2-pentene, *trans*- and *cis*-2-phenyl-2-pentene, and 2-phenyl-1-pentene** were also prepared in high purity from appropriate ketones.

**1-Chlorocyclohexene-2,6,6- $d_2$  and Phenyllithium.** 1-Chlorocyclohexene-2,6,6- $d_2$  (4.5663 g, 0.03815 mole) and 100 ml of 1.00 *M* phenyllithium (0.100 mole) in ether were heated at  $150 \pm 10^\circ$  for 1.3 hr. The reaction products included 2.13 g (46.6%; XEA,  $90^\circ$ , 35 cc/min) of 1-chlorocyclohexene-2,6,6- $d_2$  and 0.79 g (12.5%) of deuterated 1-phenylcyclohexene. Both compounds were isolated utilizing

preparative glpc. The nmr and infrared spectra of the recovered chloride were virtually identical with those of the starting material. Proton nmr analysis of the deuterated 1-phenylcyclohexene indicated the presence of  $0.82 \pm 0.09$  deuteron and  $1.93 \pm 0.11$  deuterons in the olefinic and saturated ring positions, respectively.

## Proton Transfers in Dipolar Aprotic Solvents. III. Transfers from Triphenylmethane in Dimethyl Sulfoxide Solution<sup>1,2</sup>

Calvin D. Ritchie and R. E. Uschold

Contribution from the Department of Chemistry, State University of New York at Buffalo, Buffalo, New York 14214. Received January 25, 1967

**Abstract:** The reactions of triphenylmethane with *t*-butoxide, *n*-propoxide, and dimsyl ions in dimethyl sulfoxide solution have been studied. Triphenylmethane reacts with dimsyl ion and *n*-propoxide ion to form trityl anion with second-order rate constants of  $8 \times 10^3$  and  $6 \times 10^3 M^{-1} \text{sec}^{-1}$ , respectively. The reaction of triphenylmethane with *t*-butoxide ion is too slow to measure under our reaction conditions, and an upper limit of  $8 \times 10^2 M^{-1} \text{sec}^{-1}$  is set on the rate constant for this reaction. Equilibrium constants for the reactions of triphenylmethane with dimsyl ion, *t*-butoxide ion, and *n*-propoxide ion are  $1.6 \times 10^4$ , 0.5, and 0.1, respectively.

As part of a continuing study of solvent effects on the rates of proton transfer reactions, we have measured the rates and equilibrium constants for the reactions of triphenylmethane with dimsylcesium, potassium *t*-butoxide, and potassium *n*-propoxide in dimethyl sulfoxide solution. Since the results obtained are pertinent to a number of recently reported studies of rates and equilibria of carbon acids,<sup>3</sup> we wish to report these data now. Several corrections are made to a preliminary report of this work.<sup>4</sup>

### Experimental Section

All materials were purified, stored, and handled under an atmosphere of purified argon.<sup>5</sup>

**Materials.** Dimethyl sulfoxide was purified by the method previously described,<sup>6</sup> and was found to contain less than  $5 \times 10^{-4}$  *M* acidic and basic impurities, and less than 20 ppm of water.

Dimsylcesium solutions of ca. 0.3 *M* were prepared from cesium amide as previously described.<sup>5</sup> Less concentrated solutions were prepared by dilution. The ultraviolet spectrum of a  $2.4 \times 10^{-3}$  *M* solution of cesium dimsyl in a 0.1-mm cell showed an absorption shoulder at 260  $m\mu$  ( $\epsilon = 1.5 \times 10^3 M^{-1} \text{cm}^{-1}$ ), and no peaks or shoulders at longer wavelengths. The 60-Mc nmr spectrum of a 0.24 *M* solution showed a single sharp peak for the solvent and no other visible bands within 800 cps on either side of the solvent peak. Any band with an intensity of as much as 0.5% of that of the solvent would have been seen. The infrared spectrum of a 0.24 *M* solution of dimsylcesium *vs.* pure dimethyl sulfoxide showed a single band at  $840\text{--}850 \text{ cm}^{-1}$  ( $\epsilon \approx 1.2 \times 10^3 M^{-1} \text{cm}^{-1}$ ) which we believe to be due to the S–O stretch of the dimsyl ion.

Potassium *t*-butoxide (MSA Research Corp.) was twice sublimed under vacuum at ca.  $100^\circ$  prior to use.

Potassium *n*-propoxide was prepared by reaction of metallic potassium with dry deoxygenated *n*-propyl alcohol, followed by removal of excess *n*-propyl alcohol under vacuum. The resulting product was dried under vacuum at ca.  $100^\circ$  for 3 hr. Titration of a weighed sample of the alkoxide with aqueous standard acid indicated a purity of better than 99.5%.

Triphenylmethane was recrystallized from ethanol and dried under vacuum prior to use.

A sample of triphenylmethane- $d_1$  was kindly supplied by Professor P. T. Lansbury. Infrared analysis of the material showed greater than 90% isotopic purity.

**Apparatus.** Equilibrium measurements were carried out on a Cary Model 14 spectrophotometer fitted with the mixing cell apparatus diagrammed in Figure 1, and further described below.

Kinetic measurements were carried out on a small-scale stop-flow apparatus which we have previously described.<sup>6</sup>

**Equilibrium Measurements.** Solutions of triphenylmethane (the concentrations of triphenylmethane in the various measurements ranged from  $5 \times 10^{-3}$  *M* to ca.  $10^{-4}$  *M* in each determination) were added incrementally by means of a micrometer syringe, whose tip extended into the bulb of the apparatus shown in Figure 1, to 10.0 ml of the base solutions contained in the mixing cell. The solutions were mixed after each addition by simply tipping the cell back and forth several times. Care was taken that the solutions did not contact the rubber serum cap through which the syringe was inserted.

Plots of absorbance at 495  $m\mu$ , the wavelength of maximum absorption of the trityl anion, *vs.* concentration of triphenylmethane added gave straight lines whose slopes are the apparent extinction coefficients,  $\epsilon'$ . Several experiments utilizing ca.  $10^{-1}$  *M* solutions of dimsylcesium gave the true extinction coefficient of the trityl anion,  $\epsilon$ , as  $3.12 \times 10^4 M^{-1} \text{cm}^{-1}$ . At lower concentrations of dimsyl anion, the observed apparent extinction coefficients can be used to calculate the ratio of trityl anion to triphenylmethane concentrations in the solution by eq 1.

$$(\text{Ar}_3\text{C}^-)/(\text{Ar}_3\text{CH}) = \epsilon'/(\epsilon - \epsilon') \quad (1)$$

This technique of measurement is necessary because of small amounts of impurities present which react with either the trityl anion or triphenylmethane. The fact that non-zero intercepts are obtained in the plots of absorbance *vs.* concentration show the presence of such impurities. One such plot is shown in Figure 2.

ce the equilibrium constant for the reaction of triphenylmethane with dimsyl ion has been obtained, then the equilibrium constant for the reactions of alcohols with dimsyl ion, and thus, with triphenylmethane, can be obtained. Analogous experiments to those described above in which triphenylmethane is added to solutions of the alkoxides are used to obtain the ratio of trityl ion to triphenylmethane concentrations at given alkoxide concentrations. These ratios and the equilibrium constant for the dimsyl-triphenylmethane reaction, the concentration of dimsyl ion at given concentrations of added alkoxide can be calculated, and from this, desired equilibrium constants are evaluated.

Values obtained for the various equilibrium constants are listed in Table I. The precision and accuracy of the data are discussed below.

Table I. Equilibrium Constants at 25° for the Reactions

Figure 2. Absorbance at 495 m $\mu$  vs. concentration of triphenylmethane in  $1.64 \times 10^{-3} M$  dimsylcesium in DMSO.

**Kinetic Measurements.** Solutions of known concentration of base and of triphenylmethane were prepared under an argon atmosphere and transferred to gas-tight syringes and then into the stop-flow apparatus. The reactions were followed by the appearance of the absorbance of the trityl anion at 495 m $\mu$ . Details of the general procedure used on the stop-flow apparatus have been given previously.<sup>6</sup>

In all runs, the concentration of base was much greater than the equilibrium concentration of trityl ion and the kinetics observed were those of pseudo-first-order reversible reactions. In the reactions with dimsyl ion, treatment of the data was straightforward using eq 2

$$\ln (C_a^{\infty} - C_a) = -k_p(C_0/C_a^{\infty})t + \ln C_a^{\infty} \quad (2)$$

where  $C_a^{\infty}$  is the concentration of trityl ion at equilibrium,  $C_a$  is the concentration of trityl ion at time  $t$ , and  $C_0$  is the initial concentration of triphenylmethane. The second-order rate constant for the reaction is equal to the pseudo-first-order constant,  $k_p$ , divided by the concentration of base. Some typical data for the reaction of dimsyl ion are shown in Table II.

<sup>a</sup> Slope of the plot of  $\ln (C_a^{\infty} - C_a)$  vs. time (sec). <sup>b</sup> Ratio of trityl ion concentration at equilibrium to initial triphenylmethane concentration. In each run, the initial concentration of triphenylmethane was ca.  $3 \times 10^{-4} M$ .

The reaction of triphenylmethane with solutions of the alkoxides involves simultaneous reactions with dimsyl ion and alkoxide ion since appreciable amounts of dimsyl ion are formed by reaction of

the alkoxide with solvent. In each kinetic run, we have calculated the concentration of dimsyl ion present from the observed ratio of trityl ion to triphenylmethane concentrations at equilibrium in the reactions. Knowing the concentration of dimsyl ion and the rate constant for reaction of dimsyl ion, the observed first-order rate constants in alkoxide solutions can be corrected for the reaction of dimsyl ion and the second-order rate constants for reaction of the alkoxides calculated. This calculation involves the implicit assumption that the concentration of dimsyl ion does not change during the run. Since a dilution is involved in mixing the reactants in the stop flow, and since the ratio of concentration of dimsyl ion to that of alkoxide is concentration dependent, the assumption is that the alkoxide-solvent equilibrium is established much more rapidly than reaction with triphenylmethane. The constancy of the observed rate constants with varying initial concentration of base provides support for this assumption, as does the observed linearity of the kinetic plots. The data obtained for the reactions of the alkoxides are summarized in Table III.

<sup>a</sup> Ratio of trityl ion to triphenylmethane concentration at equilibrium. The initial concentrations of triphenylmethane were from  $2.5 \times 10^{-3} M$ . <sup>b</sup> Concentration of dimsyl ion, calculated from  $R$ . <sup>c</sup> Pseudo-first-order rate constant defined by eq 2. <sup>d</sup> Pseudo-first-order rate constant for reaction with alkoxide ion. <sup>e</sup> Second-order rate constant for reaction with alkoxide ion.

The reaction of triphenylmethane- $d_1$  with dimsyl ion was also studied. This reaction involves formation of trityl ion simultaneous with hydrogen-deuterium exchange, and the rate expression cannot easily be put into the form of a plot. The integrated rate expression is given by eq 3

$$C_a^\infty - C_a = C_0 \{ (k_1 - k_1') / [k_1(C_0/C_a^\infty) - k_1'] \} e^{-k_1 t} + \{ k_1(C_0 - C_a^\infty) / [k_1(C_0/C_a^\infty) - k_1'] \} e^{-k_1(C_0/C_a^\infty)t} \quad (3)$$

where  $k_1$  is the pseudo-first-order rate constant for reaction with triphenylmethane,  $k_1'$  is the analogous constant for reaction of triphenylmethane- $d_1$ , and the other symbols are defined as in eq 2.

Rate constants were calculated by means of the method of steepest descents using a program written in Fortran IV language for this particular problem. A single kinetic run gave values for both  $k_1$  and  $k_1'$  independent of the value previously obtained for the rate constant for the undeuterated compound. An average value of  $k_H/k_D = 4.7$  was obtained at 25°. Rate constants for the reaction of the hydrogen compound calculated from these data were in good agreement with the independently determined value.

**Sources of Error and Accuracy of Data.** The very basic carbanion solutions dealt with in the present work are extremely sensitive to small amounts of impurities. It is known that oxygen reacts with triphenylmethane anion to produce hydroperoxide anions<sup>3a</sup> very rapidly. In addition, any compound which could act as even a weak acid ( $pK < 30$ ) would react with dimsyl ion to make our solutions less basic than we expect on the basis of titrations for dimsyl ion.

The fact that the plots obtained from the titrations of the base solutions with triphenylmethane, as typically shown in Figure 2, have intercepts at  $ca. 10^{-4} M$  indicates that we do not have appre-

ciable amounts of oxygen in the solutions used there. Since equilibrium constants calculated from the equilibrium concentrations in the kinetic runs agree with those determined by the titration technique fairly well, we may assume that appreciable amounts of oxygen were not present in these runs. Titrations of the solvent for acidic impurities<sup>8</sup> would have shown the presence of any acid with a  $pK$  up to  $ca. 25$ . Standardization of the dimsyl solutions by titration of formanilide in dimethyl sulfoxide and by titration with standard acid in water ensures that no acidic species with  $pK$  less than  $ca. 21$  is present.

Sulfides, sulfones, and water probably all have  $pK$ 's greater than 20 and less than that of dimethyl sulfoxide, and could reasonably go undetected and yet cause serious errors in the measurements reported here. Although water would have been detected at concentrations greater than  $ca. 10^{-3} M$  (18 ppm), there could be enough present to cause some difficulty. We have observed, however, that the addition of a drop of water to a  $5 \times 10^{-4} M$  solution of dimsylcesium causes a marked cloudiness of the solution. It therefore appears that cesium hydroxide is probably too insoluble to cause difficulty in base solutions of greater than  $ca. 10^{-3} M$ . We believe that the most likely source of error is the presence of traces of dimethyl sulfone. It would be interesting to know the  $pK$  of this compound.

Steiner<sup>7</sup> has reported a value for the equilibrium constant of the reaction of triphenylmethane with dimsyl ion as  $3 \times 10^4$ . In view of the difficulties mentioned above, we are satisfied with the agreement within a factor of 2 of our value with this one.

If Steiner's value for the equilibrium constant of the reaction of triphenylmethane with dimsyl ion is used in place of the value reported in this paper, the equilibrium constants for the reactions with the alcohols and dimsyl ion would be increased by a factor of 2, as would the rate constant for the reaction of dimsyl ion with triphenylmethane. These errors, however, would have little effect on the reported values for the rate and equilibrium constants for the reactions of the alkoxides with triphenylmethane.

In any case, the fair agreement of our values for the equilibrium constants with those reported by Steiner indicates that the values reported in the present paper are accurate to within a factor of  $\sim 2$ . Considering the difficulties of the measurements, and for the present purposes, we are content with this accuracy.

## Discussion

In a preliminary report of this work,<sup>4</sup> we overlooked the possibility of the reactions of the alkoxides with solvent to form appreciable amounts of dimsyl ion in solution.<sup>8</sup> The rate and equilibrium constants reported there are, therefore, completely in error. The two most serious errors are in the reported values for the reverse rate constants of the reactions of the alkoxides and in the value for the rate of reaction of *t*-butoxide.

The fact that *t*-butoxide contributes virtually nothing to the rate of formation of trityl ion in solutions of potassium *t*-butoxide is quite surprising and raises the question of the identity of the active base in other studies of proton abstraction in solutions of *t*-butoxide.<sup>1</sup> Since *n*-propoxide reacts with triphenylmethane quite rapidly, even though it is a weaker base than *t*-butoxide, it appears that the slowness of reaction of *t*-butoxide must be due to a steric effect. Examination of molecular models shows that this is a reasonable postulate, and, in fact, Streitwieser has suggested that a steric effect may be responsible for the slowness of reaction of methoxide ion with triphenylmethane in methanol solution.<sup>9</sup> It seems possible, also, that the reactions of both *n*-propoxide and dimsyl ion with triphenylmethane are subject to a steric effect if Streitwieser's suggestion is correct.

(7) E. C. Steiner, preprint of paper to be presented in Petroleum Chemistry Section, 153rd National Meeting of the American Chemical Society, Miami, Fla., April 1967.

(8) This possibility was pointed out to us by Dr. E. C. Steiner. We would like to express our appreciation to him for this suggestion, and for many later discussions and suggestions.

(9) A. Streitwieser, Jr., *Progr. Phys. Org. Chem.*, **3**, 58 (1965).

Data have been reported<sup>9,10</sup> which allow the calculation of a second-order rate constant of *ca.*  $10^{-9} M^{-1} \text{sec}^{-1}$  for the reaction of triphenylmethane with methoxide ion in methanol at 45°. We can, therefore, estimate that *n*-propoxide in dimethyl sulfoxide reacts at least  $10^{14}$  times faster than does methoxide in methanol with triphenylmethane. This tremendous rate enhancement must be attributed to a solvent effect if we reasonably assume that methoxide and *n*-propoxide would react at the same rate in a given solvent. (Unfortunately, the solubility of potassium methoxide in pure dimethyl sulfoxide is too low to allow easy measurement of its reactions.) With the analogous assumption that the basicity of methoxide and *n*-propoxide would be nearly the same in a given solvent,<sup>11</sup> we can estimate that the change of solvent from methanol to dimethyl sulfoxide increases the basicity of *n*-propoxide by a factor of not more than  $10^{11}$ . If one uses Steiner's recently reported<sup>7</sup> value of 26.9 for the *pK* of methanol in DMSO with the value of 18.3 for the *pK*

of methanol in methanol,<sup>6</sup> the increase in basicity of methoxide is only 8.6. We therefore conclude that factors other than solvation of the alkoxide<sup>3c</sup> contribute to the enhanced rates of proton abstraction on going from hydroxylic to nonhydroxylic solvents.

A reasonable explanation of the origin of this extra rate-enhancing factor is the postulate of the necessity of solvent reorganization which we have recently used to explain the enhanced rates of reactions of nucleophiles with carbonium ions in nonhydroxylic solvents.<sup>6</sup> In a hydroxylic solvent, the base must be hydrogen bonded to solvent molecules. At the transition state, this solvation is lost and compensation by solvent-solvent hydrogen bonding has not fully occurred. Thus, the rate of reaction is slowed in both directions. In the reverse direction, solvent molecules which are in the initial state hydrogen bonded to other solvent molecules must break away and start to reorganize to solvate the products.

As we have pointed out previously,<sup>6</sup> this idea is a simple extension of the concepts suggested by earlier workers.<sup>12</sup>

## Proton Exchange of Triethylammonium Ion in Aqueous Solution<sup>1</sup>

E. K. Ralph, III, and Ernest Grunwald

Contribution from the Lecks Chemical Laboratories, Brandeis University, Waltham, Massachusetts 02154. Received January 13, 1967

**Abstract:** Rates of exchange of NH protons of triethylammonium ion ( $\text{BH}^+$ ) with  $\text{H}_2\text{O}$  and  $\text{D}_2\text{O}$  have been measured by nuclear magnetic resonance techniques in acid solutions over a range of pH. The following reactions and rate constants (corrected to infinite dilution) were found:  $\text{BH}^+ + \text{OH}^-$ ,  $k_{-b} = (1.7 \pm 0.5) \times 10^{10} \text{sec}^{-1} M^{-1}$  at 30°;  $\text{BH}^+ + \text{OH}_2 + \text{B}$  (symmetrical exchange),  $k_s = (1.82 \pm 0.08) \times 10^8 \text{sec}^{-1} M^{-1}$  at 30°;  $\text{B} + \text{H}_2\text{O}^+$ ,  $k_{-a} = 2 \times 10^{10} \text{sec}^{-1} M^{-1}$  at 25°;  $\text{B} \cdot \text{HOD} + \text{D}_2\text{O} \rightarrow \text{B} \cdot \text{DOD} + \text{HOD}$ ,  $k_{H^*} = (3.1 \pm 0.5) \times 10^9 \text{sec}^{-1}$ . Of these rate constants, only  $k_s$  is considerably smaller than expected from data for methylamines, probably due to steric hindrance. Acid dissociation constants are reported for  $\text{BH}^+$  as a function of  $\text{BHCl}$  concentration;  $\text{p}K_A^\circ = 10.81$  at 25°.  $\text{H}_2\text{O}$ - $\text{D}_2\text{O}$  solvent isotope effects on  $K_A$  are discussed.

We wish to report nuclear magnetic resonance (nmr) measurements of the rate of proton exchange between triethylammonium ion and water in light and heavy water. The substrates, triethylammonium ion and triethylamine (which are in equilibrium at the given pH), are of interest because the site at which N-H proton transfer takes place in these molecules is under steric compression.<sup>2</sup> Both chemical evidence and space-filling molecular models suggest that the volume that would normally be assigned to the hydrogen atom or the unshared electron pair on nitrogen is invaded by part of an ethyl group.<sup>3</sup>

We find that the following proton transfer reactions of triethylammonium ion ( $\text{BH}^+$ ) are kinetically significant in the pH range 5-8: (i) symmetrical proton

exchange (eq 1), and (ii) reaction with hydroxide ion (2a) followed rapidly by 2b).

At pH < 1, acid dissociation produces an amine hydrate (eq 3), which subsequently exchanges its water molecule (eq 4).

(1) Work supported by the National Science Foundation under Grant GP 3921.

(2) H. C. Brown and S. Sujishi, *J. Am. Chem. Soc.*, **70**, 2878 (1948).

On comparing the new data with previously reported rate constants for similar reactions of ammonia and the

Figure 1.  $pK_A$  for triethylammonium ion as a function of triethylammonium chloride concentration, water, 25°.

methylamines,<sup>3a</sup> we find that  $k_2$  is only one-fifth the value that we would have predicted if there were no steric hindrance, while  $k_{-b}$ ,  $k_a$ , and  $k_{-a}$  are "normal."  $k_H$  also appears to be "normal"; it is smaller than the values reported for the methylamines and smoothly continues the trend for  $k_H$  to decrease with increasing number and size of alkyl substituents on nitrogen.<sup>3</sup>

## Results

In the pH range 5–8, the rate of proton exchange between triethylammonium ion and water was measured by nmr line-broadening techniques, using water of normal isotopic composition. In the pH range <1, the rate was too slow for those techniques and isotopic exchange between  $BH^+$  and  $D_2O$ – $DCl$  was measured instead. Since both measurements extended up to moderately high  $BH^+$  concentrations, we also report  $K_A$  for  $BH^+$  as a function of concentration.

**$K_A$  Measurements.** Acid dissociation constants were measured by a differential potentiometric method,<sup>4</sup> using triethylammonium chloride as the substrate.  $K_A$  is defined in eq 5, where the terms in brackets denote molar concentrations. Results are shown in Figure 1.

$$K_A = [B][H^+]/[BH^+] \quad (5)$$

Extrapolation to infinite dilution yields the thermodynamic constant,  $pK_A^\circ = 10.81$  at 25°, which may be compared with previously reported  $pK_A^\circ$  values of 10.75,<sup>5</sup> 10.87,<sup>6</sup> and 10.67<sup>7</sup> at 25°.  $K_A$  values at 30° (needed in the kinetic analysis) were obtained from the data in Figure 1 and a previously reported<sup>6</sup> value of 12.24 kcal for  $\Delta H_A^\circ$ .

**Proton Exchange, pH 5–8.** In the measurements reported in this section, the temperature was 30°, the solvent was  $H_2O$ , the solute was 0.05–0.2 *M* triethylammonium chloride, and the pH was adjusted by adding NaOH and measured with a pH meter. Under these conditions, the rate law for NH–OH proton exchange

(7) W. S. Fyfe, *J. Chem. Soc.*, 1347 (1955).

Figure 2. Plot of kinetic data for NH–OH proton exchange according to eq 8: triethylammonium ion in  $H_2O$  at 30°.

throughout the pH range 5–8 was found to be given by eq 6, where  $R$  denotes the rate of exchange (in moles/l.

$$R = k_{-b}[BH^+][OH^-] + k_2[BH^+][B] \quad (6)$$

sec). To allow for kinetic salt effects in the calculation of the rate constants, it is convenient to introduce eq 7 in which  $k^0$  (or  $K^0$ ) denotes the respective rate (or equilibrium) constant at infinite dilution, and  $y$  denotes the molar activity coefficient with respect to the infinitely dilute reference state. In (7a) and (7b), the

$$k_{-b} = k_{-b}^0 y_{BH^+} y_{OH^-} / y_{B \cdot H \cdot OH} \approx$$

$$k_{-b}^0 y_{BH^+} y_{OH^-} / y_B \quad (7a)$$

$$k_2 = k_2^0 y_{BH^+} y_B a_{H_2O} / y_{\pm} \approx k_2^0 \quad (7b)$$

$$[OH^-] = K_w^0 / [H^+] y_{H^+} y_{OH^-} \quad (7c)$$

$$K_A = K_A^0 y_{BH^+} / y_B y_{H^+} \quad (7d)$$

equal sign introduces formal expressions based on Brønsted's rate equation<sup>8</sup>; the approximate expressions that follow try to evaluate  $y_{\pm}$  for the transition-state complex in terms of measurable activity coefficients for stable model substances. In (7c),  $K_w^0$  is the autoprotolysis constant of water. On substituting eq 5 and 7 in (6) and rearranging, we obtain (8).

$$\frac{R}{[BH^+]} \frac{K_A^0}{K_A} = \frac{k_{-b}^0 K_w^0 + k_2^0 K_A^0 [BH^+]}{[H^+]} \quad (8)$$

Equation 8 was applied as follows: (a)  $[H^+]$  was computed from pH and  $y_{H^+}$ ;  $y_{H^+}$  was taken to be the same as  $y_{\pm}$  for 0.01 *M* HCl in a KCl solution<sup>9</sup> of the same ionic strength as the reaction mixture. (b) Plots were made of  $RK_A^0/K_A[BH^+]$  vs.  $[H^+]^{-1}$  at constant  $[BH^+]$ . (c) The slopes obtained in (b) were plotted vs.  $[BH^+]$ .

The result is shown in Figure 2, where the straight line is based on a weighted least-squares analysis of the data. According to (8) we identify the intercept as  $k_{-b}^0 K_w^0$ , and the slope as  $k_2^0 K_A^0$ . On introducing known values for  $K_w^0$  and  $K_A^0$ , we finally obtain  $k_{-b}^0 = (1.7 \pm 0.5) \times 10^{10} \text{ sec}^{-1} M^{-1}$  at 30° and  $k_2^0 = (1.82 \pm 0.08) \times 10^8 \text{ sec}^{-1} M^{-1}$  at 30°.

**Proton–Deuteron Exchange, pH <1.** In the measurements reported in this section, the temperature was 25°, the solvent was  $D_2O$ – $DCl$ , and the solute was 0.5–

1.8 *M* triethylammonium chloride. Exchange was followed by measuring the height, *h*, of the HOD proton nmr line as a function of time under conditions where *h* is proportional to [HOD]. Experimental plots of  $\log(h - h_i)$  vs. time were linear, within the experimental error, with slope  $k_e$ . Since the deuterium isotope was present in large excess, the conversion of  $\text{BH}^+$  to  $\text{BD}^+$  at equilibrium was virtually complete and the rate of the back-reaction,  $\text{BD}^+ \rightarrow \text{BH}^+$ , could be neglected. Thus  $k_e$  is the pseudo-first-order rate constant for the forward reaction,  $\text{BH}^+ \rightarrow \text{BD}^+$ , as in (9), where  $R^*$  is the rate of proton-deuteron exchange (in moles/l. sec).

$$k_e = R^*/[\text{BH}^+] \quad (9)$$

Experimental results are summarized in Table I. The high acidity of the reaction mixtures reduces the rate of reactions 1 and 2 to less than 5% of  $R^*$ , so that

\* The viscosity of the  $\text{Et}_3\text{NHCl}$ -DCl solution in  $\text{D}_2\text{O}$  relative to that of pure  $\text{D}_2\text{O}$ . <sup>b</sup> Computed as described in text; see eq 13.

these reactions can be neglected. The dominant mechanism for exchange consists of reactions 3 and 4, and the rate law is given accordingly by (10), where starred symbols are used to denote that the N-H compound is in  $\text{D}_2\text{O}$ . As it turned out that  $k_{\text{H}^*}/k_{-\text{H}^*}[\text{D}^+]$

$$k_e = k_{\text{H}^*}k_{\text{H}^*}/(k_{-\text{H}^*}[\text{D}^+] + k_{\text{H}^*}) \quad (10)$$

< 0.5 in all experiments, it was convenient to rewrite (10) in the form (11), where  $K_A^* = k_{\text{H}^*}/k_{-\text{H}^*}$ . According

$$k_e = K_A^*k_{\text{H}^*}/[\text{D}^+](1 + k_{\text{H}^*}/k_{-\text{H}^*}[\text{D}^+]) \quad (11)$$

to (11), at high acidities  $k_e$  varies as  $[\text{D}^+]^{-1}$ , with slope equal to  $K_A^*k_{\text{H}^*}$ ; at lower acidities there is negative curvature, which affords the value of  $k_{\text{H}^*}/k_{-\text{H}^*}$ . However, as is well known, there are substantial deviations from dilute-solution behavior at acid and substrate concentrations of the magnitude we are using (see Table I). We allowed for these deviations as follows: (a)  $k_{\text{H}^*}/k_{-\text{H}^*}$  is regarded as independent of concentration. This assumption is not crucial since  $k_{\text{H}^*}/k_{-\text{H}^*}[\text{D}^+] < 0.5$ , and it is consistent with previous measurements on trimethylammonium ion in aqueous HCl.<sup>10</sup> (b) The

$$k_{\text{H}^*} = k_{\text{H}^*}^0\eta^*/\eta^* \quad (12)$$

medium effect on  $k_{\text{H}^*}$  is given by (12), where  $\eta^*$  is the bulk viscosity of the solution and the superscript zero denotes the value of the property at zero solute concentration, as before. Equation 12 has been verified

(10) E. Grunwald, *J. Phys. Chem.*, **67**, 2211 (1963).

**Figure 3.** Plot of kinetic data for  $\text{NH-OD}$  proton exchange according to eq 14 and 15:  $(\text{C}_2\text{H}_5)_3\text{NH}^+$  in  $\text{D}_2\text{O}$ -DCl at 25°.

for other amines in  $\text{H}_2\text{O}$ .<sup>11</sup> (c) The medium effect on  $K_A^*$  was obtained from (13). This equation assumes that medium effects due to  $\text{BHCl}$  and  $\text{HCl}$  are additive

$$\log(K_A^*/K_A^{*0}) = \log(K_A/K_A^0)_{[\text{BHCl}]} + \log(K_A/K_A^0)_{[\text{HCl}]} \quad (13)$$

and evaluates the additive terms in  $\text{H}_2\text{O}$  rather than  $\text{D}_2\text{O}$ . The first term is shown as a function of  $[\text{BHCl}]$  in Figure 1. The second term was evaluated as

$$\log(K_A/K_A^0)_{[\text{HCl}]} = -0.32[\text{HCl}]$$

on the basis of Arnett and Mach's  $H_0'''$  acidity function.<sup>12</sup> For anilines it has been shown that medium effects on  $K_A$  due to  $\text{HCl}$  in  $\text{H}_2\text{O}$  and  $\text{DCl}$  in  $\text{D}_2\text{O}$  are closely similar.<sup>13</sup>

Let us define a parameter  $k_e(\text{cor})$  according to (14).

$$k_e(\text{cor}) = k_e K_A^{*0}\eta^*/K_A^*\eta^{*0} \quad (14)$$

It then follows from (a) to (c) above that (11) can be recast in the form

$$k_e(\text{cor}) = K_A^{*0}k_{\text{H}^*}^0/[\text{D}^+](1 + k_{\text{H}^*}/k_{-\text{H}^*}[\text{D}^+]) \quad (15)$$

The plot of  $k_e(\text{cor})$  vs.  $[\text{D}^+]^{-1}$  based on the experimental data is shown in Figure 3.  $K_A^{*0}k_{\text{H}^*}^0$  is evaluated from the limiting slope at high acidity as  $(1.45 \pm 0.2) \times 10^{-2}$ ;  $k_{\text{H}^*}/k_{-\text{H}^*}$  is evaluated from the curvature as  $0.14 \pm 0.07$ . The precision measures include our estimate of determinate errors resulting from the treatment of medium effects. During the course of this work we tried various schemes for making the corrections, including making no correction at all. The initial slope,  $K_A^{*0}k_{\text{H}^*}^0$ , was always between 0.012 and 0.018. The curvature, and therefore  $k_{\text{H}^*}/k_{-\text{H}^*}$ , was far less well defined and in one scheme even appeared to be zero.

**Evaluation of  $K_A^{*0}$  and the Rate Constants** According to the theory represented above  $K_A^{*0}$  is the "equilibrium constant" for reaction 16 in dilute solution.

We now wish to evaluate  $K_A^{*0}$  from  $K_A^0$  (eq 17) and established theories of the  $\text{H}_2\text{O}$ - $\text{D}_2\text{O}$  solvent isotope

(11) M. T. Emerson, E. Grunwald, M. L. Kaplan, and R. A. Kromhout, *J. Am. Chem. Soc.*, **82**, 6307 (1960).

effect.<sup>14-17</sup> To solve the relevant ratio (18), we intro-

duce the parameter  $L$ , defined in (19), which has been evaluated<sup>15</sup> as 11.0 at 25°. The result is (20), with  $\Phi$

$$\frac{K_A^{*0}}{K_A^0} = \frac{[\text{B}\cdot\text{HOD}][\text{D}_2\text{O}][\text{H}_2\text{O}][\text{BH}^+\cdot\text{OH}_2]}{[\text{B}\cdot\text{HOH}][\text{H}_2\text{O}][\text{D}_2\text{O}][\text{BH}^+\cdot\text{OD}_2]} \quad (18)$$

$$L = [\text{H}_3\text{O}^+]^2[\text{D}_2\text{O}]^2/[\text{D}_2\text{O}]^2[\text{H}_2\text{O}]^2 \quad (19)$$

defined in (21). Note that  $\Phi$  is a fractionation factor

$$K_A^{*0}/K_A^0 = L^{-1/2}\Phi \quad (20)$$

$$\Phi = \frac{[\text{B}\cdot\text{HOD}][\text{D}_2\text{O}]^{1/2}[\text{BH}^+\cdot\text{OH}_2]}{[\text{B}\cdot\text{HOH}][\text{H}_2\text{O}]^{1/2}[\text{BH}^+\cdot\text{OD}_2]} \quad (21)$$

for specific water isotopes in different microscopic environments: adjacent to B, adjacent to  $\text{BH}^+$ , or in bulk solvent. We now wish to show that  $\Phi$  is approximately unity.

Within the framework of the quoted theories,<sup>14-17</sup> we may assume that hydrogen isotope fractionation factors are independent of the macroscopic solvent medium and, therefore, of the microscopic environment. Moreover, for water isotopes the distribution at isotopic equilibrium is essentially statistical.<sup>15</sup> Thus, when each molecule exists in an aqueous environment,  $K$  for reaction 22 has the statistical value of 4.

On the same basis, when each molecule is adjacent to B,  $K'$  for the analogous reaction 23 has the statistical value of unity. Moreover,  $[\text{B}\cdot\text{HOD}] = [\text{B}\cdot\text{DOH}]$

and, in view of  $K' = 1$ , both are equal to  $[\text{B}\cdot\text{HOH}]^{1/2}[\text{B}\cdot\text{DOD}]^{1/2}$ . Thus we may rewrite (21) in the form

$$\Phi = \frac{[\text{B}\cdot\text{DOD}]^{1/2}[\text{D}_2\text{O}]^{1/2}[\text{BH}^+\cdot\text{OH}_2]}{[\text{B}\cdot\text{HOH}]^{1/2}[\text{H}_2\text{O}]^{1/2}[\text{BH}^+\cdot\text{OD}_2]} \quad (24)$$

Each of the three factors in (24) is a fractionation factor involving  $\text{H}_2\text{O}$  and  $\text{D}_2\text{O}$  in a different microscopic environment. Thus, if fractionation factors are indeed independent of the environment (as suggested by the success of the theory<sup>14-17</sup>),  $\Phi = 1$ .

Applying eq 20, we then find that  $K_A^{*0} = K_A^0 L^{-1/2} = 4.7 \times 10^{-12}$ . Using this value and results given in the previous section, we obtain  $k_{\text{H}}^{*0} = (3.1 \pm 0.5) \times 10^9 \text{ sec}^{-1}$  at 25° in  $\text{D}_2\text{O}$  and  $k_{\text{A}}^{*0} = 2 \times 10^{10} \text{ sec}^{-1} M^{-1}$  at 25° in  $\text{D}_2\text{O}$ . Both rate constants are of a magnitude appropriate to diffusion-controlled processes in an aqueous medium and should vary approximately inversely with the viscosity, as assumed above (eq 12). Thus, to obtain  $k_{\text{H}}^0$  and  $k_{\text{A}}^0$  in  $\text{H}_2\text{O}$ , we multiply the above values by the relative viscosity  $\eta_{\text{D}_2\text{O}}/\eta_{\text{H}_2\text{O}}$  or 1.23 at 25°.

## Discussion

Kinetic and thermodynamic constants for proton transfer of ammonia, the methylamines, and triethylamine are compared in Table II. For ammonia and the methylamines,  $k_{\text{B}}^0$  and  $k_{\text{A}}^0$  are of the correct magnitude for diffusion-controlled reactions.<sup>18,19</sup> The new values of  $k_{\text{B}}^0$  and  $k_{\text{A}}^0$  for triethylamine fit smoothly into this pattern. The fact that they are slightly smaller than those for the substrates of lower molecular weight is plausible in view of the lowering of molecular mobility and "steric factor" for reaction<sup>20</sup> that accompanies the increase in alkyl size. Clearly, whatever steric hindrance exists in triethylamine or its conjugate ion is insufficient to alter the diffusion-controlled mechanism of the respective reactions with hydrogen ion or hydroxide ion.

It is probable that the reaction measured by  $k_2$  involves one water molecule, as stated in eq 1.<sup>3,21</sup> For ammonia and the methylamines, the rate constant  $k_2$  varies monotonically with base strength as measured by  $K_{\text{B}}$ , as shown in Table II.<sup>21b</sup> From this monotonic

<sup>a</sup>  $K_{\text{B}} = [\text{BH}^+][\text{OH}^-]/[\text{B}]$ ; data based on Table I, ref 3. <sup>b</sup> Units:  $\text{sec}^{-1} M^{-1}$ . <sup>c</sup> Assume that  $k_{\text{H}}^{*0}/k_{\text{H}}^0 = k_{\text{A}}^{*0}/k_{\text{A}}^0 = \eta_{\text{H}_2\text{O}}^2/\eta_{\text{D}_2\text{O}}^2 = 1.23$ . <sup>d</sup> Data at 20°; see ref 18. <sup>e</sup> Data at 25° based on Table I, ref 3. <sup>f</sup> Present work, 25°. <sup>g</sup> Present work, 30°.

relationship we would expect that a base of the strength of triethylamine reacts with  $k_2 \approx 9 \times 10^8 \text{ sec}^{-1} M^{-1}$  at 25°. Since the actual value of  $k_2$  for triethylamine is only  $1.8 \times 10^8 \text{ sec}^{-1} M^{-1}$  at 25°, there seems to be a (possibly steric) retardation of  $k_2$  by a factor of one-fifth. As a matter of fact, when models of the transition-state complex  $\text{Et}_3\text{N}\cdot\text{H}_2\text{O}\cdot\text{HNEt}_3^+$  are constructed from space-filling atomic models, it is apparent that there is significant steric hindrance, both in formation and solvation of the transition-state complex.

## Experimental Section

**Materials.** Deuterium chloride was prepared by the addition of dichlorodimethylsilane (Aldrich) to 99.5 mole %  $\text{D}_2\text{O}^{22}$  (Matheson Coleman and Bell).  $\text{H}_2\text{O}$  was distilled from KOH in all-glass ap-

(20) M. Eigen and K. Kustin, *J. Am. Chem. Soc.*, 82, 5952 (1960).

(21) (a) Z. Luz and S. Meiboom, *J. Chem. Phys.*, 39, 366 (1963). (b) If OH bond breaking is more important in the transition state than B-H bond breaking  $(\text{BH}^+\cdot(\text{OH}^-)\cdot\text{HB}^+)$  makes an important contribution) we expect  $k_2$  to increase with basicity, as found. It should be noted also that the data in Table II have not been corrected for statistical factors (for example,  $g = 4$  for the unsolvated ammonium ion). The relationship of  $k_2/g$  vs.  $K_{\text{B}}$  is not monotonic. However, there is some question whether the statistical factor for the solvated ion is the same as  $g$  for the unsolvated ion.

(22) W. H. Greive and K. F. Sporek, *J. Chem. Educ.*, 43, 381 (1966).

paratus. Triethylammonium chloride (Eastman) was recrystallized three times from absolute ethanol.

**pH Measurements.** A Beckman research pH meter was used. The pH of the reaction mixtures was measured in a small glass reservoir fused directly to the top of the nmr sample tube. A glass-Ag|AgCl combination electrode (Beckman Model 39030) was used in all measurements.

**Proton Exchange in  $H_2O$ .** The rate of  $NH-OH$  proton exchange between triethylammonium ion and water was determined from nmr measurements of exchange broadening of the dominant water line. The exchange broadening was taken as  $T_2^{-1} - T_1^{-1}$ .  $T_2$  and  $T_1$  were measured by spin-echo techniques and rates were calculated as described previously.<sup>22</sup> The chemical shift between  $NH$  and  $OH$  protons was found to be 4.32 ppm in moderately dilute aqueous solution at 30°. The rate calculations also required knowledge of  $J_{NH}$ , the  $^{14}N-H$  spin-spin coupling constant, and of  $T^1$ , the relaxation time of the  $^{14}N$  nucleus in triethylammonium ion. However, the result is not sensitive to these variables and semiquantitative esti-

mates are sufficient. We used the values,  $J_{NH} = 55$  Hz and  $T^1 = 2.5 \times 10^{-8}$  sec, that were obtained for trimethylammonium ion. (Actual measurements were made in methanol; the  $T^1$  value obtained in methanol was then corrected for the change in solvent viscosity to yield the value listed above.)

**Proton-Deuteron Exchange in  $D_2O-DCI$ .** Production of  $HOD$  in  $D_2O-DCI$  after introduction of triethylammonium chloride was measured by repeated scanning of the  $HOD$  proton nmr line in quasi-slow passage. A known weight of  $BHCl$  salt was introduced quickly into an nmr sample tube containing a known amount of  $D_2O-DCI$  at room temperature (25°). The mixture was stirred at once to dissolve the  $BHCl$ , and placed in the sample probe of the nmr magnet. Scanning of the  $HOD$  line was begun immediately. Since the  $D_2O$  initially contained ca. 0.5 M  $HOD$ , the plot of  $HOD$  signal height vs. time consisted of two distinct regions: (1) an initial, rapid, increase (with time constant  $T_1$ ) as the  $HOD$  protons in the sample attain equilibrium with the magnetic field; (2) a subsequent, slower, increase as the  $HOD$  concentration increases due to exchange with  $BH^+$ . This second portion was used to evaluate  $k_e$ .  $T_1$  for the  $HOD$  protons in representative reaction mixtures was found to be 5–7 sec.

## Nuclear Magnetic Resonance Spectroscopy. Benzene- $^{13}C^{14}$

Frank J. Weigert<sup>1b</sup> and John D. Roberts

Contribution No. 3466 from the Gates and Crellin Laboratories of Chemistry, California Institute of Technology, Pasadena, California 91109.

Received January 23, 1967

**Abstract:** The high-resolution  $^{13}C$  spectrum of benzene has been analyzed. The long-range carbon-proton coupling constants,  $J_{CCH} = +1.0$  Hz,  $J_{CCCH} = +7.4$  Hz, and  $J_{CCCCH} = -1.1$  Hz, have been related to proton-proton coupling constants in selected model compounds.

The practical use of  $^{13}C$  nuclear magnetic resonance has been hindered by low natural abundance of this nucleus (1.1%), low inherent sensitivity to nmr detection (1.6% relative to protons at constant field), and long relaxation times. Various methods have been used to overcome these difficulties including the use of enriched materials,<sup>2</sup> observation of the spectrum under rapid-passage conditions in either the dispersion or absorption mode<sup>3</sup> (which sacrifices resolution for better signal-to-noise ratios), complete proton decoupling<sup>4</sup> which enhances the signal-to-noise ratios at the expense of coupling information, internuclear double resonance,<sup>5</sup> and flow techniques.<sup>6</sup> The development of field-frequency stabilization techniques<sup>7</sup> has made time-averaging<sup>8</sup> techniques both possible and practical.

Previously reported  $^{13}C$  spectra of benzene were obtained either under rapid-passage conditions<sup>3</sup> and showed only a broad doublet due to the one-bond C-H coupling, or with proton decoupling<sup>4</sup> and gave only a single line. Bernstein<sup>9</sup> has recently studied the

proton spectrum of 2,3,4,5-tetradeuterio-1,2- $^{13}C_2$ -benzene and has determined the four coupling constants in this AA'XX' system. The especially interesting result is the two-bond coupling  $J_{CCH}$  which was found to be +1.0 Hz. The one-bond coupling  $J_{CH}$  has been determined by several workers and is  $\sim 159$  Hz.<sup>3,10</sup>

### Experimental Section

The benzene sample used in this study contained 10% carbon disulfide and 10% tetramethylsilane (v/v). The sample was degassed and sealed under nitrogen in a 10-mm, precision-bore sample tube.<sup>11</sup>

The deuteriobenzenes were obtained from Merck Sharpe and Dohme of Canada.

The spectrometer used in this work was a special instrument developed for us by F. Nelson and V. Burger of Varian Associates and features a digital frequency sweep for  $^{13}C$  at 15 MHz provided by a Hewlett-Packard 5110-5100A frequency synthesizer controlled by a Varian Associates V-4355 digital programmer. The probe was double tuned to 15 and 60 MHz with the 60 MHz for field-frequency stabilization being derived from the stable driver frequency of the synthesizer. The field was locked by conventional techniques to the proton resonances in the sample, in the present case to tetramethylsilane. Spectra were accumulated on a Varian C-1024 computer of average transients. A block diagram of the spectrometer system is shown in Figure 1.

Comparison spectra for the seven-spin system of  $^{13}C$  and six protons were calculated using the Swalen-Reilly NMRIT<sup>12</sup> program

## Digital Frequency Sweep N.m.r. Spectrometer

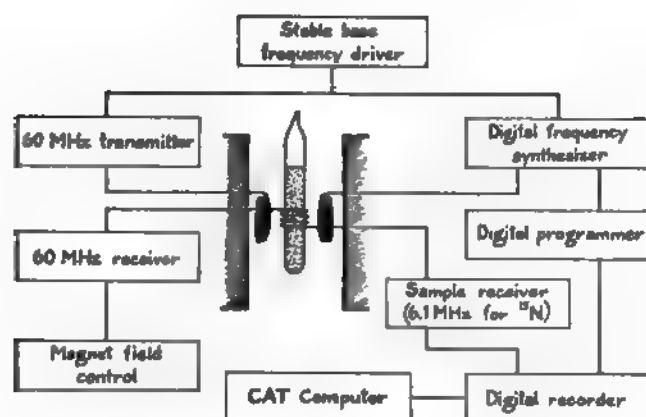

Figure 1. Digital frequency sweep nmr spectrometer.

Figure 2. (a) Natural abundance  $^{13}\text{C}$  spectrum of benzene showing the high-frequency half, taken with a sweep rate of 0.25 Hz/sec for 67 scans using TMS as internal reference at 60,006,000 Hz. The left edge of this spectrum is at 15,084,550 Hz and the right edge is at 15,084,525 Hz. (b) Calculated spectrum obtained with the parameters in Table I.

with an IBM 7094 computer and the resulting spectra were plotted on a CalComp plotter.

## Results and Discussion

The chemical shift of benzene- $^{13}\text{C}$  relative to internal carbon disulfide in the sample used in this work was found to be  $968.0 \pm 0.3$  Hz, or 64.1 ppm at 15.1 MHz. One-half of the experimental spectrum of benzene is shown in Figure 2a. Because of the complexity of this spectrum, it was found helpful to study some deuterated benzenes to aid in the interpretation. The  $^{13}\text{C}$  spectrum of 1,2,3,5-tetradeuteriobenzene, which was particularly useful in this respect, is shown in Figure 3. The carbons attached to deuterium appear as a broad triplet, in contrast to the previous observation<sup>13</sup> that such carbons cannot be observed at all because of extremely short relaxation times. The carbons directly attached to a proton show the effect of long-range cou-

(13) H. Spiesecke and W. G. Schneider, *J. Chem. Phys.*, **35**, 731 (1961).

Figure 3. Natural abundance spectrum of 1,2,3,5-tetradeuteriobenzene after 217 scans. The outer four lines arise from  $^{13}\text{C}$ -H while the middle three lines arise from  $^{13}\text{C}$ -D.

pling to the other proton in the molecule. Since all proton-proton, proton-deuterium, and carbon-deuterium couplings in this particular case are small compared to the carbon-proton couplings, the three-bond coupling constant  $J_{\text{CCCH}}$  was determined to be  $\pm 7.4$  Hz from a first-order analysis of the spectrum. The magnitude of this coupling is confirmed by the observation of a doublet of triplets for the carbons attached to protons in 1,3,5-trideuteriobenzene, with the small coupling constant again being 7.4 Hz.

The  $^{13}\text{C}$  spectrum of benzene was calculated using the proton-proton coupling constants determined from observation of the  $^{13}\text{C}$  satellites in the proton spectrum<sup>14</sup> or interpolation of the observed variation of proton-proton coupling constants of substituted benzenes with electronegativity,<sup>15</sup> two long-range coupling constants determined from deuterated benzenes, and a value for the four-bond coupling constant calculated from the difference between  $J_{\text{CCCH}}$  and  $J_{\text{CCH}}$  and the known value of  $J_{\text{CCH}}$ . The parameters used are shown in Table I and the calculated spectrum in Figure 2b. The agreement is excellent.

Table I. Benzene Coupling Constants Calculated by the Extended Hückel Theory

type have been performed on benzene and the results are shown in Table I.

The agreement between observed and calculated coupling constants is rather poor. The discrepancies seem general for  $\pi$ -electronic systems and have been accounted for<sup>18</sup> through neglect of  $\sigma$ - $\pi$  interaction, coupling through the  $\pi$  system which is not taken into account, and other factors.

Since the available data for proton-proton couplings are much more extensive than for carbon-proton coupling, it would be particularly desirable to be able to relate couplings involving  $^{13}\text{C}$  and protons to those involving only protons. A theoretical basis for this has already been described,<sup>18</sup> but the treatment has only been applied to aliphatic systems, and with limited success. Assuming that the carbon in question is in the same steric and electronic environment as a certain proton and that the Fermi contact term is the dominant coupling mechanism, the two coupling constants such as  $J_{\text{CCCH}}$  and  $J_{\text{HCCCH}}$  can be related by a single parameter which depends only on the hybridization of the carbon in question. Assuming a specific form for the carbon 2s orbital (a Slater orbital with exponent 3.25 was used), the constant relating the two couplings<sup>18</sup> was determined as 0.40 for an  $\text{sp}^2$  carbon giving the relationship  $J_{\text{CCCH}} = 0.4J_{\text{HCCCH}}$ . Previously this relationship has only been applied to intramolecular comparison of coupling constants,<sup>19</sup> but with the correct choice of model compounds, there seems to be no reason why it should not be extended to intermolecular comparisons. Several compounds (II-IV) are proposed as models for benzene

(18) G. J. Karabatsos, J. D. Graham, and F. M. Vane, *J. Am. Chem. Soc.*, **84**, 37 (1962).

(19) The poor agreement originally found by Karabatsos and co-workers<sup>18</sup> may be due to the choice of model compounds and neglect of the possibility of opposite signs for some of the coupling constants.

(I). The predicted benzene coupling constants based on the relevant coupling constants for these compounds are given in Table II.

Table II. Relationship of CH and HH Coupling Constants

	$J_{\text{CCH}}$	$J_{\text{CCCH}}$
Benzene (obsd)	+1.0	+7.4
Calcd from $J_{\text{HH}}$ in		
Ethylene <sup>a</sup>	+1.0	+7.6
Butadiene <sup>b</sup>	+0.7	+6.8
Propene <sup>c</sup>	+0.8	+6.8

<sup>a</sup> R. M. Lynden-Bell and N. Sheppard, *Proc. Roy. Soc. (London)*, **A269**, 385 (1962). <sup>b</sup> R. T. Hobgood and J. H. Goldstein, *J. Mol. Spectry.*, **12**, 76 (1964). <sup>c</sup> P. C. Lauterbur and R. J. Kurland, *J. Am. Chem. Soc.*, **84**, 3405 (1962).

The choice of a correct model compound for the four-bond coupling is difficult. Although the analogy is imperfect, a negative sign has been predicted for the four-bond, proton-proton coupling constant in allene<sup>20</sup> which is 7.1 Hz.<sup>21</sup> There are two equivalent paths possible for transmission of the spin information in allene, and they are expected to give an additive effect. On this basis a single path with three intervening  $\text{sp}^2$ -hybridized carbon atoms should lead to a proton-proton coupling constant of -3.5 Hz which with Karabatsos' formulation leads to prediction of -1.4 Hz for the four-bond coupling constant  $J_{\text{CCCH}}$  in benzene.

The general agreement is excellent and it appears profitable to investigate further the relation between the magnitudes of the two- and three-bond, carbon-proton coupling constants with those in analogously constituted systems involving proton-proton coupling.

**Acknowledgments.** We thank Professor G. W. Robinson for loaning us samples of the deuterated benzenes used in this investigation and George Petersson for a copy of his program for extended Hückel molecular orbital calculations.

# The Proton Magnetic Resonance Spectra of Arylcarbonium Ions. Neighboring Group Anisotropies and Charge Distributions<sup>1</sup>

D. G. Farnum<sup>2</sup>

Contribution from the Department of Chemistry, Cornell University, Ithaca, New York 14850. Received November 12, 1966

**Abstract:** The nmr spectra of a number of arylcarbonium ions in fluorosulfonic acid solution are analyzed with the aid of a computer. The chemical shift parameters obtained are compared with some previously reported. They are interpreted with the aid of a double toroid ring-current model for the anisotropy of neighboring phenyls. They are then discussed with reference to charge distributions as determined by some molecular orbital models.

The proton nmr spectra of arylcarbonium ions have been the subject of both qualitative<sup>3</sup> and quantitative<sup>4</sup> investigations for several years. Among the earliest attempts at quantitative analysis was that of O'Reilly and Leftin<sup>4c</sup> on triphenylcarbonium ion. A considerable dispute over the assignment of chemical shifts and coupling constants in triphenylcarbonium ion<sup>3c,4c</sup> seemed to subside with the publication by Dehl, *et al.*,<sup>4c</sup> of deuterium-labeling studies and a computer-simulated spectrum. It seemed to us that the more sophisticated techniques now available in the rapidly developing field of nmr spectroscopy warranted a reinvestigation of some arylcarbonium ions. Impetus was also provided by the fact that early attempts to interpret the chemical significance of the chemical shifts were based on the wrong chemical shift assignments and an incomplete model for the ring-current effect.<sup>4c</sup>

ions and suggested that the interpretation previously reported in the literature required some modification.<sup>4a</sup> We here report a detailed analysis of the nmr spectra of several arylcarbonium ions at 60 MHz, including a reanalysis of triphenylcarbonium ion at 60 and 100 MHz. We make an attempt to discuss the observed chemical shifts in terms of realistic models for the geometry, ring-current effect, and charge distribution in these ions.

## Experimental Section

**Materials.** Chlorosulfonic acid was distilled immediately before use; fluorosulfonic acid was distilled over anhydrous potassium fluoride, placed in oven-dried, glass-stoppered bottles, sealed with paraffin, and stored in a drybox. All transfers of fluorosulfonic acid were accomplished in the drybox by pipet. Carbonium ion precursors were the carbinols with the exception of compounds 1 (phenylpropionic acid), 2 (benzoic acid), 3 (benzophenone), 4 (acetophenone), and 7 (1,1-diphenylethylene) in Table I. Solid pre-

cursors were commercial samples twice recrystallized and dried under vacuum before use. Liquid samples were distilled and a middle cut was taken. Gas chromatographic analysis in all cases resolved only one component in greater than 99% purity. Phenyl-dimethylcarbinol was obtained as a crystalline solid, mp  $32.5-33.5^\circ$ , by two sublimations. Nmr samples were made up to 1 to 10% concentration by the addition of a methylene chloride solution of the precursor to vigorously stirred acid at  $-40^\circ$ . The acid layer was drawn off for use.

**Determination of the Spectra.** The proton nmr spectra were determined at 60 and 100 MHz on the Varian A-60 or HA-100 instruments. At low concentrations (1%) the Varian CAT was employed to bring out the spectrum. It was demonstrated that the chemical shifts (relative to tetramethylammonium fluoroborate internal standard taken as  $\tau$  6.87<sup>4a</sup>) and general appearance of the spectra were relatively insensitive to concentration (from 1 to 10% for 4, 7, and 9 of Table I) and temperature (from  $-40$  to  $+40^\circ$ ).

Figure 1. Nmr spectrum (60 MHz) of benzoic acid in chlorosulfonic acid.

Figure 2. Nmr spectrum (60 MHz) of benzophenone in chlorosulfonic acid.

In those cases which could be determined in both acids, the shifts were nearly the same, but the spectra in fluorosulfonic acid were better resolved (presumably because of the greater fluidity). The structures of the carbonium ions were assured by the reproducibly characteristic nmr patterns, the near identity of the ultraviolet spectra of the diluted solutions of 4 and 9 (Table I) with those reported in the literature,<sup>5</sup> and recovery of the parent alcohol in 60% yield or better by quenching in iced aqueous base in the cases of triphenylcarbinol (5), benzhydrol (8), benzophenone (3), and benzoic acid (2). The spectrum of methylphenylcarbonium ion (7) has appeared in the literature.<sup>4a</sup> Our spectrum was similar in appearance, but better resolved. Spectra were determined on both 300 Hz and 250 Hz nominal scale widths, calibrated with known standards to determine the actual scale widths.

**Analysis of the Spectra.** Nmr spectra were analyzed with the aid of the nmr simulation computer program, LAOCOON II, devised by Bothner-By.<sup>6</sup> Spectra were computed on a Control Data Corp. 1604 computer, traced on a curve-plotter, and compared with the determined spectra. A line-width factor of 0.8 (approximately equal to width at half-height in Hertz) gave computed spectra of comparable appearance to the experimental ones. Iterations to

(6) We thank Dr. Bothner-By for providing us with the program deck and instructions for LAOCOON II.

Figure 3. Nmr spectrum (60 MHz) of acetophenone in chlorosulfonic acid.

Figure 4. Nmr spectrum (60 MHz) of triphenylcarbinol in fluorosulfonic acid (upper curve) and computer-simulated spectrum (lower curve) using parameter values given in Table I.

determine the best fit were performed separately at 60 and 100 MHz for triphenylcarbonium ion. The results at the different frequencies were in close agreement (within 0.5 Hz). To assist in the preliminary choice of parameters 20 spectra with identical approximate coupling constants but differing chemical shifts were computed. An approximate fit to one of these provided the starting point for the iteration procedure. In the cases of acetophenone (phenylmethylhydroxycarbonium ion), benzoic acid (phenyldihydroxycarbonium ion), and phenyldimethylcarbonium ion, separation of the peaks was sufficient to assign chemical shifts by inspection after the initial comparison. For benzophenone (diphenylhydroxycarbonium ion) the poorer resolution did not warrant an attempt at a closer assignment than that obtained by estimation from the first comparison. The determined and simulated spectra for the several carbonium ions are compared in Figures 1-8. The chemical shifts and coupling constants are given in Table I. The assignment of the *ortho*, *meta*, and *para* protons rests firmly on the large (7-8 Hz) coupling of the *ortho* proton to one *meta* proton, the large (7-8 Hz) coupling of the *meta* proton to both *ortho* and *para* protons, and the low intensity of the peaks corresponding to the single *para* proton.

Figure 5. Nmr spectrum (100 MHz) of triphenylcarbinol in fluorosulfonic acid (upper curve) and computer-simulated spectrum (lower curve) using parameter values given in Table I.

Figure 6. Nmr spectrum (60 MHz) of 1,1-diphenylethylene in fluorosulfonic acid (upper curve) and computer-simulated spectrum (lower curve) using parameter values given in Table I.

There is some variance in the values reported for triphenylcarbinol ion from several sources. These values are compared in Table II. The chemical shifts obtained in this work are in reason-

Figure 7. Nmr spectrum (60 MHz) of diphenylcarbinol in chlorosulfonic acid (upper curve) and computer-simulated spectrum (lower curve) using parameter values given in Table I.

able agreement with those of Schaeffer and Schneider<sup>4b</sup> and Berry, *et al.*,<sup>4a</sup> while coupling constants are quite comparable with those obtained by the latter authors. The variations probably are the result of different solvents and reference standards as well as the difficulty of analyzing the 60-MHz spectrum without the aid of a computer.

## Discussion

Several general features emerge from the data from nmr analysis of several arylcarbonium ions as given in Table I. The chemical shift value for the phenyl protons of phenylpropionic acid in sulfuric acid solution ( $\tau$  2.80) is given as a reference point. As expected, all the arylcarbonium ion chemical shifts fall below this value, and the  $p$ -proton resonance moves progressively downfield as the electron-releasing ability of the substituents on the  $\alpha$ -carbon decreases. This qualitative correlation of the position of the  $p$ -proton resonance with the electron demands placed on the phenyl by the

3. Nmr spectrum (60 MHz) of phenyldimethylcarbinol in trifluoroacetic acid at  $-40^\circ$  (upper curve) and computer-simulated spectrum (lower curve) using parameter values given in Table I.

ium ion is expected and has been noted in the literature.<sup>4a</sup> The *o*- and *m*-proton resonances are much broader and are apparently significantly perturbed by the anisotropies of the  $\alpha$  substituents.<sup>4a</sup> Thus for the diphenyl (8), hydroxydiphenyl (3), methyldiphenyl (7), and triphenylcarbonium ion (6), the *o*-proton resonances ( $\tau$  1.54, 1.88, 1.93, and 2.32) fall successively upfield, apparently independently of the effect of the positive charge on the phenyl. This order, however, does correlate with the size of the  $\alpha$  substituent, and, therefore, with the angle of twist of the substituents from coplanarity. Increased twisting from coplanarity (up to about  $45^\circ$ ) will result in increased upfield shift of the *o*-protons by neighboring phenyl anisotropy as illustrated in Figure 9. For the *meta* and *para* shifts (2.02, 2.17, 2.10, and 2.14) the influence of the positive charge and anisotropy might be better understood; thus the correlation is not expected to be as simple. As an incidental point, all the coupling constants fall within the ranges quoted in the literature for aromatic compounds,<sup>7</sup> in spite of the major perturbation by the positive charge.

In order to examine the quantitative validity of some of the ideas suggested in the previous paragraph, it was necessary to develop a quantitative picture of the effect of the neighboring phenyl anisotropy effect as a function of the angle of twist of the phenyls. A model for this was based upon a modification of the Johnson-Waugh-Fessenden<sup>8</sup> double-loop ring-current model which has been described in another publication<sup>9</sup> and applied to the di- and triphenylcyclopropenium ions.

Figure 10 depicts the neighboring ring-current effect on the angle of twist for triphenylcarbonium ion as calculated using this model (a double doughnut-shaped circulating charge of radius and cross-sectional area equal to  $1.4 \text{ \AA}$ ). The calculation determines the effect of both the near and remote neighbor phenyls on the *o*-, *m*-, and *p*-proton, assuming that all phenyls are twisted the same angle from coplanarity.<sup>9</sup> The effect for a diphenylcarbonium ion should be one-half the values in Figure 10, provided only that interchange

<sup>a</sup> Column labeled abs gives values in parts per million downfield from the phenyl hydrogens of phenylpropionic acid. Column labeled rel gives values relative to *para* chemical shifts = 1.00. <sup>b</sup> Corrected for the neighboring ring-current effect at the angle in question. <sup>c</sup> Simple Hückel molecular orbitals. <sup>d</sup> Modified  $\omega$  technique.<sup>15</sup> <sup>e</sup> Self-consistent-field calculations.<sup>16</sup> <sup>f</sup> Chemical shifts are calculated as the sum of the contributions from all carbon atoms using Musher's equations.<sup>12</sup>

to set the twist angles for diphenyl-, dihydroxydiphenyl-, methyldiphenyl-, and triphenylcarbonium ions at 25, 30, 35, and 45°, respectively, corrected the chemical shifts for the determined ring-current effects, and re-examined the thus-obtained order of chemical shifts. The results are shown in Table III. Although the *m*- and *p*-protons now correlate, and the *o*-protons are more nearly in line, the correction is not sufficient to bring complete order to the *o*-proton chemical shifts. We have been unable to find alternative reasonable choices of twist angles which improve the order. It is possible that a residual effect of the  $\alpha$ -hydroxyl substituents is causing a downfield shift since the oxygenated cations (2, 3, and 4) appear at too low field, with the dioxygenated case 2 being particularly low.

With the chemical shifts corrected for neighboring ring-current effects in hand, it was possible to examine their correlation with predicted charge distributions in these ions. Two refinements of earlier work in this field<sup>3,4</sup> were attempted in this investigation. First, earlier efforts had considered only the effect of the positive charge of the directly attached carbon atom. However, Musher has claimed<sup>12</sup> that all nearby positive charges have a significant effect. Therefore, using Musher's equations,<sup>12</sup> we set up a computer program which would calculate the chemical shifts at the *o*-, *m*- and *p*-protons resulting from point charges of specified values at all the carbon atoms in the mono-, di-, and triphenylcarbonium ions. Second, earlier attempts<sup>4</sup> have determined the theoretical charge distribution in di- and triphenylcarbonium ions based upon *planar* molecules rather than realistically twisted ions. We therefore calculated the Hückel charge densities for these ions at twist angles of 25, 35, and 45°.<sup>13</sup>

The results of these combined calculations are summarized in Table IV.

Again a qualitative picture can be drawn. Thus, the larger relative<sup>14</sup> downfield chemical shift observed for the *o*-protons of phenyldimethylcarbonium ion is correctly reproduced by both the Hückel and the  $\omega$ -technique<sup>15</sup> calculations, but not by the SCF<sup>16</sup> method. The moderate chemical shift of the *m*-proton is in accord with all the calculations, in spite of the absence of charge at that position in the Hückel approximation. The relative chemical shifts for a 35° twisted diphenylcarbonium ion are extraordinarily well reproduced by the Hückel model, while much more difficulty is encountered with triphenylcarbonium ion, which shows more dispersal of charge to the *para* position than expected. Unfortunately, calculations by the  $\omega$ -technique and SCF method for these twisted cations are not yet available for comparison. Since several approximate models have been interposed between the raw data and the numbers being compared in Table IV, it seems wise to be cautious in attempting any more quantitative analysis of the results.

An incidental observation of some interest was made on solutions of the phenyldimethylcarbonium ion in fluorosulfonic acid. These solutions were stable only below -20°, as evidenced by the smooth, reproducible, rapid conversion of their characteristic nmr spectrum above that temperature to a new, well-resolved, and entirely different spectrum illustrated in Figure 11. The irreversible conversion was accompanied by a barely perceptible lightening of the lemon yellow color

(14) The discrepancy between the absolute values and the observed values is not surprising, since the Musher equations contain no correction for the solvent dielectric effect on the charge.

of the solution. The new species was identified as the dimeric phenylmethyl-(2-phenylisobutyl)carbonium ion (10) by isolation of the corresponding olefin (11) in good yield by quenching the solution in iced aqueous sodium hydroxide. The olefin was purified by gas chromatography and characterized by its mass spectrum (parent peak,  $m/e$  236) and nmr spectrum ( $\tau$  2.0–2.9, multiplet, area = 10.0; 4.13, quartet,  $J = 2$  Hz, area = 0.6; 8.02, doublet,  $J = 2$  Hz, area = 2.6; 8.80, singlet, area = 6.0) which left no doubt of its structure. The methyl and methylene resonances of the carbonium ion appeared at  $\tau$  6.18 (broad, area ca. 2), 6.61 (broad, area ca. 3), and 8.47 (sharp, area ca. 6).

The nmr spectrum of carbonium ion 10 deserves notice. It is entirely different from any which we have encountered in this work in that no phenyl resonance appears at the low-field position usually observed for *o*-protons, nor is there a clear separation between the phenyl conjugated with the carbonium ion center and that attached to the quarternary carbon. A rapid equivalencing of the phenyls by methyl migration (10a  $\rightleftharpoons$  10b) cannot account for the results because the

methyl resonance signals are sharp and discrete, nor can they be the result of dimeric association, since the spectrum is the same at concentrations from 1 to 10%. We suggest that the unusual nmr spectrum of 10 is accommodated by a folded geometry, as in 10c ( $\text{R} = \text{CH}_3$ ), in which the noncationic phenyl is associated with the cationic phenyl analogously to a charge-transfer complex or a solvation association. A similar explanation, named a "space-polarization effect,"

Figure 11. Nmr spectrum (60 MHz) of phenyldimethylcarbonium ion dimer.

has been offered by Williams for the anomalous ultraviolet spectrum of phenyl- $\beta$ -phenylethylcarbonium ion (10c,  $\text{R} = \text{H}$ ).<sup>17</sup> The required folded geometry is readily achieved in molecular models.

In summary, the following conclusions seem justified on the basis of the treatment reported in this paper. (1) The *p*-proton resonance provides a reasonable qualitative measure of the extent of dispersion of positive charge onto the phenyl group of a phenylcarbonium ion. (2) When suitable corrections are made for neighboring ring-current effects and nonplanar geometries, the positive charges calculated by the simple Hückel approximation account for the ring chemical shifts of phenyldimethyl- and diphenylcarbonium ion in an entirely satisfactory way. However, triphenylcarbonium ion exhibits somewhat more dispersal of charge to the *para* position than expected. (3) Taken together, the results suggest that the twist angles of the polyphenylcarbonium ions examined are greater than 25°, and perhaps as high as 45° from coplanarity.

# Hyperfine Structure in the Electron Spin Resonance Spectra of Reduced Porphins

N. S. Hush<sup>1a</sup> and J. R. Rowlands<sup>1b</sup>

Contribution from the Department of Inorganic Chemistry, Bristol University, Bristol, England, and Southwest Research Institute, San Antonio, Texas 78206.  
Received January 19, 1967

**Abstract:** Electron spin resonance spectra with well-resolved hyperfine structure have been obtained by reduction of zinc tetrabenzporphyrin and zinc etioporphyrin I with sodium in tetrahydrofuran solution. Hyperfine structure has also been observed in the spectrum obtained from etioporphyrin I under the same conditions. The paramagnetic species in each case is considered to be either a trinegative ion of the porphyrin or a phlorin dianion  $\text{PH}^{2-}$  in which a hydrogen atom is attached to a methine carbon atom of the porphyrin skeleton.

Electron addition to porphyrin (P) or metal porphyrin (MP) molecules leads to the formation of a series of negative ions of increasing charge. Closs and Closs<sup>2</sup> studied the reduction of zinc  $\alpha,\beta,\gamma,\delta$ -tetraphenylporphyrin in tetrahydrofuran and prepared salts of the mononegative and dinegative ions, corresponding to uptake of one and two electrons, respectively. Dodd and Hush<sup>3</sup> have reported the formation of mono- and dinegative ions of complexes of a variety of substituted porphins, including metal derivatives of etioporphyrin, tetraphenylporphyrin, tetraazaporphin, tetrabenzporphyrin, and phthalocyanine. Evidence of two further one-electron steps, corresponding to the formation of trinegative and tetranegative ions, has been obtained by Clack and Hush.<sup>4</sup> Felton and Linschitz<sup>5</sup> have also reported polarographic results on tetraphenylporphyrin and etioporphyrin complexes which are in agreement with those of ref 3. Recent work on the reduction of metal phthalocyanines<sup>6</sup> shows that salts of negative ions containing from one to four additional electrons can be isolated from solution.

The typical molecular symmetry of divalent metal complexes of porphins is  $D_{4h}$ . In some complexes the symmetry is lower, usually because the central metal atom lies slightly out of the plane of the ring. However, perturbations of this type are small and in either case the lowest empty ligand orbital has e symmetry. This means that up to four electrons can be accommodated in this orbital, in agreement with the experiment. An interesting feature of these ions is that the energies of

the disproportionation reactions are positive and remarkably constant over a range of porphyrin structures whose  $\text{M}^{II}$  is a closed-shell ion. An interpretation of this in terms of electron interaction energies has been given by Hush.<sup>7</sup> It should also be mentioned that for some divalent transition metal porphins<sup>5,6</sup> and phthalocyanines<sup>8,9</sup> the first reduction step corresponds to reduction of the metal to the +1 oxidation state; in subsequent steps, this is followed by electron addition to the ring, forming  $\text{M}^{\text{IP}2-}$  ions, which are the analogs of the  $\text{M}^{\text{IP}}$  ions of porphyrin complex of closed-shell metal ions. These will not be further considered here, as they present special problems of interpretation.

The purpose of this communication is to present some results of measurements of the electron spin resonance spectra of solutions containing reduced porphins.

Closs and Closs<sup>2</sup> established that salts of tetraphenylporphyrin<sup>-</sup> and tetraphenylporphyrin<sup>2-</sup> were respectively paramagnetic and diamagnetic in tetrahydrofuran. Similar results have been found in the phthalocyanine series, both for phthalocyanine itself and for closed-shell metal complexes.

The electron spin resonance spectra of a number of mononegative ions of tetraphenylporphyrin and etioporphyrin derivatives, mostly obtained by electrolytic reduction in dimethyl sulfoxide solution, have been reported by Felton and Linschitz.<sup>5</sup> These exhibit no hyperfine structure and have  $g$  values which, although close to the free-spin value, deviate by small but significant amounts in a number of complexes. Similar results have been obtained for metal phthalocyanine negative ions in dimethylformamide solution,<sup>6</sup> also obtained by electrolytic reduction. The lack of hyperfine structure in these spectra has been explained on the basis that the electron is in a doubly degenerate orbital and that the separation of the hyperfine lines in the monoanion in which the spin density is averaged by "fast switching" perturbations (internal or external) to reflect the molecular symmetry is predicted to be smaller than individual line widths.

We have observed similar single-line electron spin resonance spectra of porphyrin mononegative ions obtained by reduction with sodium metal in tetrahydrofuran solution. The solutions ( $10^{-3}$ – $10^{-4}$  M) were prepared by a technique described elsewhere.<sup>9</sup> The electron spin resonance measurements were made at room temperature using a Varian V-4500 X-band spectrometer. Three molecules have so far been studied: zinc tetrabenzporphyrin, zinc etioporphyrin I, and etioporphyrin I (Figure 1). For the latter molecule, the initial reaction with sodium is replacement of the two central ring hy-

atoms;<sup>3</sup> reduction of the disodium complex proceeds in successive one-electron steps.

the reduction was allowed to proceed past the gative ion stage in dilute solution, different were obtained. In this case, the electron spin ce spectra of the solution began to exhibit hyper- icture, which was better resolved as the reduc- ceeded.

course of the reaction was qualitatively followed rving the characteristic color changes.<sup>3</sup> Thus, : etioporphyrin, hyperfine structure appeared e green mononegative ion was almost entirely d to the crimson dinegative ion. The spectra l for zinc tetrabenzporphyrin and zinc etiopor- olutions are shown in Figures 2 and 3, respec-

These exhibit similar hyperfine patterns. xtrum obtained from etioporphyrin solutions 4) is not so well resolved as the previous two.

irst possibility to consider is that these spectra e of ions produced by the addition of three s to the lowest  $e_g$  antibonding orbital. It is ediatly obvious, however, why the trinegative  $^{3-}$  should yield an electron spin resonance n with hyperfine structure whereas both we and orkers<sup>4</sup> have shown that the mononegative ion ingle-line electron spin resonance spectrum with rvable structure. Furthermore, the observed e is not compatible with that predicted for a on. As in the  $MP^-$  ion (as mentioned above) e electrons in the trinegative ion  $MP^{3-}$  are in a degenerate orbital,<sup>4</sup> and the spin density distri- ill depend on the type of external or internal ation coupling the two components. The aver- ration of the lines predicted<sup>5</sup> for a system frozen

$e_{gx}$  (or  $e_{gy}$ ) configuration for an average com-  $(1/\sqrt{2})(e_{gx} + e_{gy})$ , or for "rapid switching"

the two components, is less than line widths bserved for ions with  $^3E$  ground states. Never- our observed spectra for zinc tetrabenzporphyrin : etioporphyrin (Figures 5 and 6, respectively)

Figure 4. Hyperfine structure of reduced etioporphyrin I.

are at least compatible with the interaction of an un- paired electron with four equivalent nitrogen atoms and four equivalent protons with coupling constants as in Table I, if some allowance is made for some minor inconsistencies in the relative intensity distributions. These discrepancies could well arise from incomplete averaging to zero of both the anisotropic hyperfine interactions and quadrupole interactions. The poor agreement between the computed spin density distribu- tion and the observed could well arise from the fact that no attempt has been made to allow for configuration interaction.

Table I. Observed and Calculated Hyperfine Splittings<sup>a</sup>

	Obsd, gauss	Calcd, gauss	
		$\delta = 0$	$\delta = 1.0$
Zinc tetrabenzporphyrin	$A_N$ 2.59		
	$A_H$ 1.55		
Zinc etioporphyrin I	$A_N$ 2.62	1.36	0.725
	$A_H$ 1.63	2.25	2.58

<sup>a</sup> Calculated values were taken from ref 4.

A second possibility to be considered is that the ion giving rise to the observed structure is the phlorin di- negative ion. It is known from previous work<sup>2,3</sup> that the dinegative ions are relatively easily protonated, and that even in apparently aprotic solvents it is difficult to obtain dilute solutions of the dinegative ions of porphins free from protonated species. Protonation of the dinegative ion of zinc  $\alpha,\beta,\gamma,\delta$ -tetraphenylporphyrin in tetrahydrofuran leads to the formation of a salt of the phlorin anion  $ZnPH^-$ , where the hydrogen has added

for the three methine hydrogen atoms ( $Q_H$ ), the nitrogen atom ( $Q_N$ ), and the methylene group ( $Q_{CH_2}$ ) are  $A_H = 2[65(2)]$ ,  $5[29(1)]$ ,  $A_N = 2[61(2)]$ , and  $A_{CH_2} = 6[79(2)]$  gauss, respectively. In computing the methylene coupling we have taken the spin density to be proportional to the square of the sum of the coefficients of the H orbital at each carbon atom, i.e., of the form  $Q(C_1 + C_2)^2$  rather than  $Q(C_1^2 + C_2^2)$ .<sup>8</sup> These couplings would lead to a spectrum with a width of 40 gauss which is far in excess of the experimental spectrum. Furthermore, in order to fit the total number of lines observed, further hyperfine interactions with peripheral methylene groups would have to be invoked, which would make the situation worse.

It is clear on the basis of this discussion that much further experimental work on a range of substituted porphyrin structures must be carried out before definitive

analysis can be attempted. It is also clear that simple Hückel spin density calculations are not sufficiently accurate for meaningful theoretical predictions to be made of the nature of these porphyrin reduction products.

We note in conclusion that Mauzerall and Feher<sup>10</sup> have obtained a transient paramagnetic radical by irradiation of porphyrin-phlorin mixtures in glycerine solution. This is probably the neutral phlorin radical PH. The identification of intermediates of this type is essential for an understanding of porphyrin oxidation-reduction reactions, and for an understanding of the electron spin resonance signals observed in photosynthetic materials.<sup>11</sup>

## Photochemical Conversion of 7-Methoxycycloheptatriene to 1-Methoxybicyclo[3.2.0]hepta-3,6-diene<sup>1</sup>

G. W. Borden,<sup>2a</sup> O. L. Chapman, R. Swindell,<sup>2b</sup> and T. Tezuka

*Contribution from the Department of Chemistry, Iowa State University of Science and Technology, Ames, Iowa 50010. Received February 7, 1967*

**Abstract:** The photochemical conversion of 7-methoxycycloheptatriene to 1-methoxybicyclo[3.2.0]hepta-3,6-diene is shown to involve initial photoisomerization to 1-methoxycycloheptatriene followed by photochemical valence isomerization to the bicyclic product. Irradiation of 1-methoxycycloheptatriene gives 7-methoxycycloheptatriene and the bicyclic valence tautomer. The sigmatropic reactions of order [1,7] involved in the interconversion of 7-methoxycycloheptatriene and 1-methoxycycloheptatriene are shown to arise from singlet states. The 1,7-hydrogen shift by which 1-methoxycycloheptatriene is converted to 7-methoxycycloheptatriene is remarkably specific. No 2-methoxycycloheptatriene could be detected. The photochemical valence tautomerization of 1-methoxycycloheptatriene to 1-methoxybicyclo[3.2.0]hepta-3,6-diene is shown to arise from a singlet state of the triene.

Photoisomerization of cycloheptadienes, cycloheptatrienes, and tropolones to unsaturated derivatives of bicyclo[3.2.0]heptane is one of the most generally applicable photochemical reactions.<sup>2</sup> Irradiation of cycloheptatriene gives both toluene and bicyclo[3.2.0]hepta-2,6-diene.<sup>3,4</sup> Toluene is the major product in the vapor phase<sup>4</sup> and the bicyclic valence tautomer in solution.<sup>5</sup> Irradiation of certain substituted cyclo-

heptatrienes gives rise to 1,5-hydrogen shifts which lead to isomeric cycloheptatrienes when substituents are present.<sup>9</sup> More complex thermal isomerizations are observed with 7,7-disubstituted cycloheptatrienes.<sup>10</sup>

We now wish to report a photoisomerization reaction which is anomalous both in solution and in the vapor phase with respect to the behavior of cycloheptatriene. Irradiation of 7-methoxycycloheptatriene or 7-ethoxycycloheptatriene in ether solution gives in each case the 1-alkoxybicyclo[3.2.0]hepta-3,6-diene. Yields in excess of 90% have been obtained, and vpc and nmr analysis of the crude reaction mixture shows that the reactions are essentially quantitative.

heptatrienes gives isomeric cycloheptatrienes by 1,7-hydrogen shifts.<sup>6-8</sup> Thermal isomerization of cyclo-

The ultraviolet spectra of the photoproducts show no maxima above 220 mμ, which suggests bridging of the ring. The nmr spectra of the photoproducts IIa and b show in each case four olefinic protons, three protons on saturated carbon, and methoxyl (IIa) or ethoxyl (IIb) protons. The presence of the cyclobutene double bond could be detected by the characteristic coupling constant (IIa, 2.9 cps)<sup>11</sup> and field position (IIa,  $\tau$  3.80; IIb,  $\tau$  3.77). The first indication that the photoproducts were not the simple valence tautomers IIIa and b was the absence of a resonance characteristic of the >CHOR group in the nmr spectra of the tetrahydro derivatives

of the photoproducts. This must mean that the alkoxy functions are at the bridgehead in the tetrahydro derivatives Va and b and consequently that the photoproducts are either IIa and b or IVa and b. A decision in favor of the 1-alkoxybicyclo[3.2.0]hepta-3,6-diene structures (IIa and b) was possible on the basis of the thermal transformations of the photoproducts. When IIa and b were dropped through a pyrolysis column preheated to 340–350° the sole products were 1-methoxycycloheptatriene (VIa) and 1-ethoxycycloheptatriene (VIb) respectively. A control experiment showed that the 7-alkoxycycloheptatrienes (Ia and b) were converted only partially to the 1-alkoxycycloheptatrienes (VIa

(11) O. L. Chapman, *J. Am. Chem. Soc.*, **85**, 2014 (1963); P. Laszlo and P. von R. Schleyer, *ibid.*, **85**, 2016 (1963); G. V. Smith and H. Kriloff, *ibid.*, **85**, 2017 (1963).

and b) under identical conditions.<sup>12</sup> Irradiation of the 1-alkoxycycloheptatrienes gave the valence tautomers IIa and b. Confirmation of the assigned structures was obtained by the sequence of reactions described below. In the reduction of the photoproducts it had been noted that the two double bonds were reduced at different rates. Addition of 1 equiv of hydrogen gave the dihydro derivative VII in which the cyclobutene double bond had been selectively reduced. The nmr spectrum of VII showed a multiplet at  $\tau$  4.30 due to the cyclopentene protons. The characteristic absorption of the cyclobutene protons ( $\tau$  3.80) was no longer present. Hydroboration followed by chromic acid oxidation<sup>13</sup> gave 1,4-cycloheptanedione (VIII). Hydroboration and oxidation of VII could give rise to two possible ketones IX and X. No evidence for the pres-

ence of X was obtained. Tetrahydrophoto- $\gamma$ -tropolone methyl ether (IX) is known to be transformed rapidly to 1,4-cycloheptanedione in acid solution.<sup>14</sup> The alternate structure IVa for the photoproduct cannot account for the formation of VIII since the oxygen functions after partial reduction, hydroboration, and oxidation of IV must be either 1,2 or 1,3 with respect to each other rather than 1,4 as required by the formation of VIII.

Irradiation of 7-methoxycycloheptatriene at low pressure in the vapor phase gave a mixture which consisted of 7-methoxycycloheptatriene (14%), 1-methoxycycloheptatriene (38%), and 1-methoxybicyclo[3.2.0]hepta-3,6-diene (48%). This was the first indication that 1-methoxycycloheptatriene might be an isolable intermediate in the formation of IIa and suggested that the reaction in solution should be monitored carefully.

The photochemical transformation of 7-methoxycycloheptatriene was monitored by ultraviolet and nmr spectroscopy and by vapor phase chromatography.<sup>15</sup> The ultraviolet spectra of the solution during irradiation show disappearance of the 255-mμ maximum of 7-methoxycycloheptatriene and appearance and decay of a maximum at about 280 mμ. Both vapor phase chromatography and nmr spectra show the formation and destruction of an intermediate (Figures 1 and 2). Isolation of the intermediate and comparison of spectra identified it as 1-methoxycycloheptatriene (VIa). Careful monitoring of the photochemical rearrangement of 7-methoxycycloheptatriene (Ia) in the early phase of the reaction showed that 1-methoxycycloheptatriene (VIa) was the sole primary product since the concentration *vs.* time plot for this substance extrapolated to zero at zero time (Figure 3).

(12) The thermal isomerization of 7-methoxycycloheptatriene has been studied in detail.<sup>14,1</sup> The first product from 7-methoxycycloheptatriene is 3-methoxycycloheptatriene and the second is 1-methoxycycloheptatriene. More extensive rearrangement would have been observed at the temperatures used except for the very short residence time in the pyrolysis column.

(13) H. C. Brown and C. P. Garg, *J. Am. Chem. Soc.*, **83**, 2951 (1961).

(14) O. L. Chapman and D. J. Pasto, *ibid.*, **82**, 3642 (1960).

(15) Under the conditions of the analysis, 7-methoxycycloheptatriene isomerized to 3-methoxycycloheptatriene. Both 1-methoxycycloheptatriene and 1-methoxybicyclo[3.2.0]hepta-3,6-diene were stable to the conditions.

lar extrapolation for 1-methoxybicyclo[3.2.0]-1,3,6-diene (IIa) did not pass through the origin (see 3). The bicyclic product (IIa) thus is a secondary product formed only after 1-methoxycycloheptatriene is formed. It should be noted that the bicyclic photoproduct is formed very early in the reaction when a relatively small fraction of the light is being absorbed by VIa. The photoisomerization of VIa to IIa must be a reasonably efficient process (see Figures 4 and 5 for nmr spectra of VIa and IIa, respectively).

No evidence for any intermediate beside 1-methoxycycloheptatriene was obtained. A sequence of two hydrogen transfer processes (known to occur readily)<sup>18,19</sup> could convert 7-methoxycycloheptatriene to 1-methoxycycloheptatriene. If this were the case, 7-methoxycycloheptatriene would be an intermediate between 7-methoxycycloheptatriene and 1-methoxycycloheptatriene. With this in mind, 3-methoxycycloheptatriene was irradiated. The reaction mixture was complex in contrast to the clean reactions of 7-methoxycycloheptatriene and 1-methoxycycloheptatriene. The crude product was separated into two fractions. The first fraction was shown to contain at least three bicyclic compounds. One was separated and identified as 1-methoxybicyclo[3.2.0]hepta-3,6-diene (IIa).

The other two bicyclic compounds were not identified. Hydrolysis of the mixture gave rise to infrared carbonyl absorptions characteristic of five-membered and four-membered ring ketones suggesting presence of enol ethers. Reduction of the mixture after work-up, bicyclo[3.2.0]heptan-6-one (XI) identified by comparison of its infrared spectrum with that of an authentic sample.<sup>18</sup> The formation of XI suggests that XII and/or XIII is present in the mixture. The second fraction consisted of a mixture of methoxy-

heptatrienes.<sup>17</sup> The nature of the photoproducts of 3-methoxycycloheptatriene makes it very clear that it is not an intermediate in the photochemical rearrangements of 7-methoxycycloheptatriene.

Irradiation of 1-methoxycycloheptatriene for short periods of time gave 1-methoxybicyclo[3.2.0]hepta-3,6-diene (IIa) and 7-methoxycycloheptatriene (Ia). Prolonged irradiation gave only the bicyclic valence tautomer IIa. A photostationary state is thus established between 7-methoxycycloheptatriene and 1-methoxycycloheptatriene which is displaced by conversion of 7-methoxycycloheptatriene to 1-methoxybicyclo[3.2.0]hepta-3,6-diene. Two points of substantial interest arise when one considers the reactions involved. First, is it that the 1,7-hydrogen shift in VI is so specific,

The mode of formation of XI is not completely clear. It might be a reductive cleavage of the ether or more likely hydrolysis of a cyclic acetal derivative of XII or XIII in work-up. The authentic sample of XI was prepared by D. L. Garin, Ph.D. Thesis, Iowa State University, 1964.

It can be argued that the mixture of methoxycycloheptatrienes is an artifact resulting from the work-up procedure. The mixture of bicyclic compounds, however, must have been formed in a photochemical reaction and clearly shows that the photochemical transformations of methoxycycloheptatriene are less specific than those of 7-methoxycycloheptatriene and 1-methoxycycloheptatriene.

Figure 1. Plot of per cent 7-methoxycycloheptatriene (Ia, Δ), 1-methoxycycloheptatriene (VIa, □), and 1-methoxybicyclo[3.2.0]hepta-3,6-diene (IIa, +) vs. time of irradiation.

i.e., why is no 2-methoxycycloheptatriene formed? Second, why is isomerization to the bicyclic valence tautomer so much more efficient when a methoxyl

group is present in the 1 position?<sup>18</sup> The specificity of the 1,7-hydrogen shift in VIa is even more dramatic when considered in the light of the lack of specificity in the reactions of 3-methoxycycloheptatriene and other substituted cycloheptatrienes.<sup>4-8</sup>

The multiplicities of the states responsible for the reversible 1,7-hydrogen shifts and the photoisomerization to the bicyclic system are of some interest. The photoisomerization of 7-methoxycycloheptatriene to 1-methoxycycloheptatriene was not sensitized by acetophenone ( $E_t \sim 74$  kcal/mole)<sup>19</sup> and was not quenched by oxygen. The photosensitization experiments with 7-methoxycycloheptatriene were very clean because the absorption of 7-methoxycycloheptatriene above 3400 Å is negligible. The filter system used had zero transmission below 3400 Å and 65% transmission at 3600 Å. All of the light was absorbed by the sensitizer, and no reaction could be detected by vpc analysis. Acetophenone ( $E_t \sim 74$  kcal/mole) should have a sufficiently high triplet energy to transfer energy to the triene. The triplet energy of cycloheptatrienes is not known but should lie between that of simple olefins (ethylene, 82 kcal/mole)<sup>20</sup> and planar trienes (*trans*-1,3,5-hexa-

(18) Photoisomerization of cycloheptatriene<sup>4</sup> in solution requires several days' irradiation while photoisomerization of 1-methoxycycloheptatriene under comparable conditions requires only a few hours' irradiation.

(20) D. F. Evans, *J. Chem. Soc.*, 1735 (1960).

Figure 2. Upper left, 7-methoxycycloheptatriene (Ia) before irradiation. Upper right, sample after irradiation for 30 min. Lower left, sample after irradiation for 120 min. Lower right, sample after irradiation for 270 min. Resonance positions are given on the  $\tau$  scale relative to internal tetramethylsilane.

Figure 3. Plot of per cent 7-methoxycycloheptatriene (Ia,  $\Delta$ ), 1-methoxycycloheptatriene (VIa,  $\square$ ), and 1-methoxybicyclo[3.2.0]hepta-3,6-diene (IIa, +) vs. time for the first 20 min of irradiation (vpc analysis).

triene, 47 kcal/mole)<sup>20</sup> and is probably somewhat closer to the latter.<sup>21</sup> Neither the conversion of 1-methoxycycloheptatriene to 7-methoxycycloheptatriene nor the conversion to 1-methoxybicyclo[3.2.0]hepta-3,6-diene was affected significantly by oxygen. No evidence for photosensitization of either process by acetophenone was obtained. The photosensitization experiments were somewhat more complicated in this case because 1-methoxycycloheptatriene ( $\lambda_{\max}$  290 m $\mu$ ) has significant absorption above 3400 Å ( $\epsilon_{3400}$  4.1) and because it gives two products. The results, however, make it clear that reaction is much slower when most of the light is absorbed by sensitizer. When enough sensitizer is present to absorb >88% of the incident light, reaction is too slow to be detected in the usual irradiation period (1 hr).

(21) The nonplanar ground state of cycloheptatrienes makes it difficult to extrapolate the available results. Furthermore, it is clear that ring size affects triplet energy (1,3-cyclopentadiene,  $E_t$  = 58.4; 1,3-cyclohexadiene,  $E_t$  = 53.5 kcal/mole).<sup>22</sup> If 7-methoxycycloheptatriene is assumed to have a singlet ( $S_1$ )-triplet ( $T_1$ ) gap of the same energy as *trans*-1,3,5-hexatriene (59.8 kcal/mole)<sup>23</sup> and the maximum (2550 Å) of the  $S_0 \rightarrow S_1$  absorption band is used as a measure of the  $S_0 \rightarrow S_1$  transition energy, the result is an estimated triplet energy of about 52 kcal/mole, which is in a reasonable range.

Nuclear magnetic resonance spectrum of 1-methoxycycloheptatriene (VIa). Calibration is on the  $\tau$  scale relative to tetramethylsilane.

It is reasonable to conclude that the reversible photochemical 1,7-hydrogen shift between 7-methoxycycloheptatriene and 1-methoxycycloheptatriene in a singlet state regardless of which compound absorbs the light. This conclusion is in accord with the recognized inefficiency of intersystem crossing in conjugated olefins.<sup>20</sup> There remains a question whether the reaction occurs *via* an electronic excited state or a vibrationally excited ground state. The fact that thermal isomerization gives products derived from 5-hydrogen atom shifts does not preclude reaction *via* a vibrationally excited ground state. No essential distinction between the two possibilities is possible, although it seems reasonable that vibrational activation would be extremely rapid in solution. Orbital symmetry arguments also suggest that the conversion of I and VI occurs *via* electronic states.<sup>22</sup> We conclude that the photochemical conversion of 7-methoxycycloheptatriene and 1-methoxycycloheptatriene probably proceeds *via* the singlet excited state of the triene in each case. The specificity of the photochemical interconversion of methoxycycloheptatriene and 1-methoxycycloheptatriene is of special interest. Orbital symmetry arguments suggest that photochemical, suprafacial, electrocyclic reactions of order [1,7] are allowed in cycloheptatrienes.<sup>22</sup> This suggestion is consistent with experimental observation.<sup>6-8</sup> A single sigmatropic shift of order [1,7] is possible for 7-methoxycycloheptatriene and leads to 1-methoxycycloheptatriene. Related sigmatropic shifts are possible for 1-methoxycycloheptatriene which should lead to 7-methoxy-

cycloheptatriene and 2-methoxycycloheptatriene. Experimentally, only the sigmatropic shift leading to 7-

Figure 5. Nuclear magnetic resonance spectrum of 1-methoxybicyclo[3.2.0]hepta-3,6-diene (IIa). Calibration is on the  $\tau$  scale relative to internal tetramethylsilane.

methoxycycloheptatriene is observed. Orbital symmetry arguments apply only to processes in which the transition state has some element of symmetry. Previously developed orbital symmetry arguments for hydrogen transfer reactions have been applied only to transfers between the terminals of systems of the type  $>\text{CH}(\text{C}=\text{C})_m$ .<sup>22</sup> In these cases the symmetry of the highest occupied molecular orbital is the controlling factor. The transition state for the conversion of VIa to Ia is asymmetric, and simple orbital symmetry arguments cannot be applied. It is interesting to note,

however, that the highest occupied molecular orbital ( $\psi_6$ , XIV) for the electronically excited nine-electron, eight-atom  $\pi$  system<sup>23</sup> is such that suprafacial hydrogen transfer from position 1 to position 7 with continuous overlap is feasible,<sup>24</sup> while suprafacial transfer from position 1 to position 2 with continuous overlap is not feasible.

Photochemical valence isomerization of conjugated dienes to cyclobutenes involves singlet excited states in certain cases and triplet excited states in others. Srinivasan has shown that a singlet excited state is the reactive species in the valence isomerization of cycloheptatriene and has provided other examples of valence

(23) The ether oxygen atom with two electrons is included in the basic  $\pi$  system.

(24) In general, for systems in which two or more sigmatropic reactions of order [1,*j*] are possible, the reaction with the highest value of *j* is favored. This may be a consequence of the greater degree of conjugation in the transition state for the process with the highest value of *j*.<sup>22</sup>

tautomerization *via* singlet excited states.<sup>4,25</sup> Schenck and co-workers<sup>26</sup> have noted photosensitization of the valence tautomerization of *cis,cis*-1,3-cyclooctadiene, and Dauben and co-workers<sup>27</sup> have demonstrated photosensitization of the valence tautomerization of 1,1-bicyclohexenyl and have provided additional examples which proceed *via* singlet excited states. Liu<sup>28</sup> has shown that the photosensitized isomerization of *cis,cis*-1,3-cyclooctadiene first gives *cis,trans*-1,3-cyclooctadiene which undergoes thermal cyclization to bicyclo[4.2.0]oct-7-ene in the manner described by Fonken and co-workers.<sup>29</sup> Liu<sup>28</sup> has suggested that a similar sequence of reactions may occur in 1,1'-bicyclohexenyl.

In the photoisomerization of 1-methoxycycloheptatriene to 1-methoxybicyclo[3.2.0]hepta-3,6-diene it is clear that the reaction is not quenched by oxygen. Addition of acetophenone to the solution slows the reaction because of light absorption by the sensitizer. No photosensitization is observed. It thus seems likely that the triplet excited state is not involved in formation of the valence tautomer IIa. This again poses the problem of electronic *vs.* vibrational excitation. Formation of 1-methoxybicyclo[3.2.0]hepta-3,6-diene is favored in solution but not in the vapor phase. This observation strongly suggests that the reaction proceeds through an electronic excited state rather than a vibrationally excited ground state. Molecular orbital arguments also suggest that an electronic excited state is the species responsible for valence isomerization.<sup>30</sup>

## Experimental Section

**Analytical Techniques.** Nuclear magnetic resonance spectra were recorded at 60 Mc on either a Varian Associates A-60 analytical nmr spectrometer or upon a Varian Associates HR-60 nmr spectrometer. Infrared spectra were recorded on a Perkin-Elmer Model 21 double-beam infrared spectrophotometer. Ultraviolet spectra were recorded on a Beckman DK-2A ratio recording spectrophotometer. Gas chromatographic analyses were performed on an F & M Model 500 programmed temperature gas chromatograph or a Perkin-Elmer vapor fractometer using helium as a carrier gas at flow rates from 40 to 100 cc/min. Individual columns and conditions of chromatography are described as they appear in the Experimental Section.

**Solvents.** Benzene (Matheson Coleman and Bell) was purified just prior to use by the method of Fieser.<sup>31</sup> Ethyl ether (Mallinckrodt) was distilled from phosphorus pentoxide and stored over sodium wire. Oxygen was removed by bubbling nitrogen gas through these solvents for 1 hr just prior to use.

**Filter Solution.** The filter solution used in this work was prepared by dissolving 0.600 g of 2,7-dimethyl-3,6-diazacyclohepta-1,6-diene perchlorate<sup>32</sup> and 25 g of potassium hydrogen phthalate in 1 l. of water. This solution (1 ml), diluted to 10 ml with water, gave 65% transmission of light at 3660 Å and no transmission below 3400 Å (1-cm path).

**Preparation of 7-Methoxycycloheptatriene (I).** Tropilidene chloride prepared by the method of Kursanov<sup>33</sup> was used to prepare 7-methoxycycloheptatriene according to the procedure of Doering and Knox.<sup>34</sup>

**Preparation of 3-Methoxycycloheptatriene.** This material was prepared in 76% yield by the method of Weth and Dreiding,<sup>34</sup> bp 74–75° (25 mm).

**Preparation of 1-Methoxycycloheptatriene (VIa).** This material was prepared in 63% yield from 7-methoxycycloheptatriene according to the method of Weth and Dreiding,<sup>34</sup> bp 77–80° (30 mm).

**Irradiation of 7-Methoxycycloheptatriene.** A solution of 8.0 g (0.065 mole) of 7-methoxycycloheptatriene in 2.0 l. of anhydrous, oxygen-free ether was irradiated with a quartz-jacketed Hanovia immersion lamp (Type A) for 8 hr. After evaporation of the solvent, the residue was distilled through a short column to give 9.4 g (92%) of 1-methoxybicyclo[3.2.0]hepta-3,6-diene [bp 39° (20 mm)]. This was the highest yield obtained. Yields varied substantially (25–92%) and seemed to depend on the amount of polymerization during distillation. Vapor phase chromatography (using internal standards) and nmr analysis of the crude product showed an essentially quantitative yield of 1-methoxybicyclo[3.2.0]hepta-3,6-diene.

*Anal.* Calcd for C<sub>8</sub>H<sub>10</sub>O: C, 78.65; H, 8.25. Found: C, 78.83; H, 8.36.

**1-Ethoxybicyclo[3.2.0]hepta-3,6-diene.** A solution of 7-ethoxycycloheptatriene (10 g) in absolute ether (2 ml) was irradiated 8 hr with a Hanovia immersion lamp (Type A) encased in a quartz immersion well. Distillation of the ethereal solution through a short Vigreux column gave 1-ethoxybicyclo[3.2.0]hepta-3,6-diene (9.1 g, 91%), bp 47° (21 mm).

*Anal.* Calcd for C<sub>8</sub>H<sub>12</sub>O: C, 79.37; H, 8.88. Found: C, 79.53; H, 8.83.

**Pyrolysis of 1-Ethoxybicyclo[3.2.0]hepta-3,6-diene.** 1-Ethoxybicyclo[3.2.0]hepta-3,6-diene (2.0 g) was dropped into a preheated (340°) vertically mounted pyrolysis column packed with Pyrex helices and swept through with a stream of dry nitrogen. The exit from the pyrolysis column was connected to a trap immersed in a Dry Ice-acetone bath. The infrared, ultraviolet, and nmr spectra of the material collected in the trap were identical with those of an authentic sample of 1-ethoxycycloheptatriene.

A control experiment in which 7-ethoxycycloheptatriene was put through the same pyrolysis column at 340° gave only 30% 1-ethoxycycloheptatriene. At 410° complete conversion to 1-ethoxycycloheptatriene was achieved. The product in this case was isolated in 71% yield.

**Pyrolysis of 1-Methoxybicyclo[3.2.0]hepta-3,6-diene.** 1-Methoxybicyclo[3.2.0]hepta-3,6-diene was pyrolyzed in the manner described above with the column preheated at 352°. The product was identified by comparison of spectra with an authentic sample of 1-methoxycycloheptatriene.

In a control experiment pyrolysis of 7-methoxycycloheptatriene at 350° in the same column gave less than 40% conversion to 1-methoxycycloheptatriene. At 420° conversion was complete and 1-methoxycycloheptatriene was isolated in 74% yield.

**1-Ethoxybicyclo[3.2.0]heptane.** Platinum oxide (20 mg) in carbon tetrachloride (3 ml) was prereduced, and 1-ethoxybicyclo[3.2.0]hepta-3,6-diene (73 mg) was added. The solution absorbed 2.08 equiv of hydrogen. After filtration, the product was isolated by preparative-scale vapor phase chromatography on a  $\frac{3}{8}$  in.  $\times$  6 ft Ucon LB 550X on Chromosorb P (1:5) column. The nmr spectrum of the product showed only protons on saturated carbon.

*Anal.* Calcd for C<sub>8</sub>H<sub>14</sub>O: C, 77.14; H, 11.43. Found: C, 76.86; H, 11.14.

**1-Methoxybicyclo[3.2.0]heptane.** Platinum oxide (20 mg) in carbon tetrachloride (3 ml) was prereduced. 1-Methoxybicyclo[3.2.0]hepta-3,6-diene (97 mg) was added. The solution absorbed 2.05 equiv of hydrogen. The product was separated by preparative-scale vpc as described above. The nmr spectrum of the product

(33) This preparation was first reported by D. N. Kursanov and M. E. Volpin, *Dokl. Akad. Nauk SSSR*, **113**, 339 (1957). Since that time, other workers<sup>34</sup> have suggested that, while this preparation yielded a compound whose chemical properties were essentially the same as tropilidene chloride, in actual fact a chlorophosphorus complex was formed with cycloheptatriene.

(34) D. Bryce-Smith and N. A. Perkins, *J. Chem. Soc.*, 1339 (1962).

(35) W. von E. Doering and L. H. Knox, *J. Am. Chem. Soc.*, **76**, 3203 (1954).

ed only protons on saturated carbon and the methoxyl

Calcd for  $C_9H_{14}O$ : C, 76.19; H, 11.11. Found: C, 76.1; H, 11.16.

**Phase Irradiation of 7-Methoxycycloheptatriene.** The system used consisted of a vacuum line containing two cold traps connected by a coil made from a 12-ft length of 10 mm (o.d.) tubing. The coil was 4 in. high and 3 in. in diameter. A lamp (Type A) was mounted in the center of the coil. 7-Methoxycycloheptatriene (1.2 g) was introduced into one trap and the other was filled with Dry Ice-acetone. The system was then evacuated to  $10^{-4}$  mm. The Dry Ice-acetone bath was then moved to the other trap and the 7-methoxycycloheptatriene slowly distilled to the coil to the other trap. This distillation was repeated and the condensed liquid was recovered. Vpc analysis showed 7-methoxycycloheptatriene (14%), 1-methoxycycloheptatriene (4%), and 1-methoxybicyclo[3.2.0]hepta-3,6-diene (48%).

**1-Methoxybicyclo[3.2.0]hepta-3,6-diene.** A solution of 1-methoxybicyclo[3.2.0]hepta-3,6-diene (2.74 g) in carbon tetrachloride containing 0.5% platinum on charcoal (50 mg) was permitted to absorb of hydrogen. Vpc analysis of the product showed one component (95%). The nmr spectrum of the product showed only traces of residual absorption due to the cyclobutene but showed a strong resonance at  $\tau$  4.30 for the cyclopentene.

The product proved to be rather sensitive and was used at step without further purification.

**Reaction of 1-Methoxybicyclo[3.2.0]hepta-3,6-diene to 1,4-Cycloheptanone.** A mixture of sodium borohydride (0.55 g) and zinc chloride (0.1 g) in anhydrous ether (20 ml) was stirred for 1.4 hr under a nitrogen atmosphere. A solution of 1-methoxybicyclo[3.2.0]hepta-3,6-diene (6.2 g) in anhydrous ether (15 ml) was added dropwise during 1 hr. After stirring for 2 hr, the hydride was destroyed with water (2 ml). A solution of dichromate (12.5 g) in sulfuric acid (4 ml of concentrated, 25 ml with water) was added over a 15-min period. After under reflux for 2 hr, the upper layer was separated, and the aqueous layer was extracted twice with ether (10 ml). The combined ether solutions were dried over magnesium sulfate fully concentrated to 20 ml. Treatment of a 5-ml portion of the solution with 2,4-dinitrophenylhydrazine in ethanolic acid gave a recrystallization from nitrobenzene-ethanol, orange crystals, mp 242–243°. These crystals were identified as 1,4-cycloheptanone by mixture point with an authentic sample and comparison of infrared. Analysis of the remainder of the ether solution by vpc showed only ether and 1,4-cycloheptanone. Vpc analysis using 1,4-cycloheptanone standard (*n*-butyl ether) gave an estimated yield of 1,4-cycloheptanone of 21% (based 1-methoxybicyclo[3.2.0]hepta-3,6-diene).

**Reaction of 3-Methoxycycloheptatriene.** A solution of 3-methoxycycloheptatriene (8.5 g) in ether (2 l.) was irradiated for 1 hr with a Hanovia mercury lamp (Type A) in a quartz immersion vaporator of the ether and distillation gave an oil (4.74 g) (44%). The oil was separated into two fractions by preparative vpc (F silicone column), A (1.23 g) and B (680 mg).

Vpc of fraction A showed the presence of three components. Careful separation of fraction A (1 g) by preparative vpc (diisodecyl phthalate column) gave 1-methoxybicyclo[3.2.0]hepta-3,6-diene (50 mg) and a mixture of two other bicyclic compounds (530 mg). Reduction of the mixture of bicyclic compounds (530 mg) in ethyl acetate (2.5 ml) containing 5% Pd-C, and removal of the solvent gave a colorless oil (500 mg).

Analysis of the oil showed the presence of at least three components. Separation of the oil by preparative-scale vpc (Ucon X column) gave fractions A-1 (50 mg), A-2 (18 mg), and A-3 (12 mg). Fraction A-1 showed only saturated protons (in  $CH_2OCH$  absorption). A-2 also showed  $OCH_3$  absorption. A-3 was identified as bicyclo[3.2.0]hepta-6-one by comparison of its infrared spectrum with that of an authentic sample. The ultraviolet absorption of fraction B suggested that the mixture of isomeric methoxycycloheptatrienes. This was confirmed by the nmr spectrum of the mixture. Comparison of the nmr spectrum of the mixture with the spectra of authentic 1-, 2-, and 3-methoxycycloheptatrienes suggested that the mixture was composed of 1-, 2-, and 3-methoxycycloheptatrienes.

A portion of A (230 mg) in ethanol (0.5 ml) and 1 *N* sulfuric acid (0.5 ml) was heated on a steam bath for 30 min. Extraction, drying, and removal of the solvent gave an oil which showed infrared absorption at 5.62, 5.78 (sh), 5.87, and 6.04  $\mu$ .

**Monitored Irradiations of 7-Methoxycycloheptatriene.** A. A solution of 7-methoxycycloheptatriene (8.0 g) in oxygen-free ether (1.75 l.) was irradiated with a Hanovia mercury lamp (Type A) in a quartz immersion well. Samples (50 ml) were withdrawn every 30 min and analyzed by ultraviolet, vpc, and nmr methods. The ultraviolet analysis showed steady decrease of the 255-m $\mu$  maximum of 7-methoxycycloheptatriene, buildup of a broad maximum at 280 m $\mu$ , and decay of the 280-m $\mu$  maximum. Vpc analysis (F silicone, 80°) gave the plots shown in Figure 1 which show the formation and destruction of an intermediate. The nmr analysis showed steady decrease in the  $OCH_3$  signal ( $\tau$  6.63) of 7-methoxycycloheptatriene, rapid formation of a new  $OCH_3$  signal ( $\tau$  6.47) at lower field and a  $CH_2$  signal ( $\tau$  7.55, doublet,  $J_{app} = 7.4$  cps)<sup>37</sup> due to 1-methoxycycloheptatriene, and slower formation of a  $OCH_3$  signal ( $\tau$  6.76) and  $CH_2$  signal ( $\tau$  7.62) due to 1-methoxybicyclo[3.2.0]hepta-3,6-diene. As the reaction progressed, the signals characteristic of 7-methoxycycloheptatriene disappeared first, then the signals characteristic of the intermediate (1-methoxycycloheptatriene) disappeared, leaving only signals due to 1-methoxybicyclo[3.2.0]hepta-3,6-diene.

B. A solution of 7-methoxycycloheptatriene (8.0 g) in ether (1.75 l.) was irradiated as described above. Samples were withdrawn every 5 min and analyzed by vpc. The results obtained are plotted in Figure 2. It is clear that 1-methoxybicyclo[3.2.0]hepta-3,6-diene is not formed until a significant amount of the intermediate (1-methoxycycloheptatriene) is formed. The bicyclic product thus is not a primary photoproduct of 7-methoxycycloheptatriene.

C. A solution of 7-methoxycycloheptatriene (8.0 g) in ether (1.75 l.) was irradiated as described above for 2 hr. Evaporation of the ether gave the crude mixture of photoproducts. The crude product showed three components (vpc). Separation of 1 g of the mixture by preparative-scale vpc gave 1-methoxybicyclo[3.2.0]hepta-3,6-diene (190 mg), 1-methoxycycloheptatriene (100 mg), and 3-methoxycycloheptatriene (thermal rearrangement product of 7-methoxycycloheptatriene, 120 mg). The products were identified by comparison of spectra with those of authentic samples.

**Irradiation of 1-Methoxycycloheptatriene.** A solution of 1.4 g (0.012 mole) of 1-methoxycycloheptatriene in 2 l. of anhydrous ether was irradiated for 9 hr with a quartz-jacketed Hanovia immersion lamp (Type A). The solution was concentrated on a rotary evaporator and distilled, giving 1-methoxybicyclo[3.2.0]hepta-3,6-diene (0.6 g, 43%) identified by comparison of nuclear magnetic resonance and infrared spectra with that of a sample prepared by the irradiation of 7-methoxycycloheptatriene. No attempt to maximize the yield was made.

**Short-Term Irradiation of 1-Methoxycycloheptatriene.** A solution of 1-methoxycycloheptatriene (500 mg) in oxygen-free benzene (250 ml) was irradiated for 1 hr using a Pyrex-jacketed Hanovia immersion lamp (Type A). The solvent was distilled off, and the nmr spectrum of the crude reaction mixture was taken. Three peaks in the methoxy region were observed and identified as being due to 7-methoxycycloheptatriene, 1-methoxycycloheptatriene, and 1-methoxybicyclo[3.2.0]hepta-3,6-diene. Integration of these three peaks showed that the 7-methoxy compound composed approximately 20% of the total product mixture. Formation of 7-methoxycycloheptatriene could also be followed by the appearance of its characteristic ultraviolet absorption at 255 m $\mu$ .

**Irradiation of 7-Methoxycycloheptatriene in the Presence and Absence of Oxygen.** A solution of 1.0 g (0.0082 mole) of 7-methoxycycloheptatriene in 240 ml of oxygen-free benzene was irradiated with a Pyrex-jacketed Hanovia immersion lamp (Type A) for 3 hr. The solvent was evaporated from a 50-ml aliquot, and the nmr spectrum of the residue was taken. The amount of reaction was estimated by comparing the integral ratios of the peaks due to the methoxy groups of I, II, and III. This integration gave the values Ia (38%), VIa (17%), and IIa (45%).

The experiment was repeated using oxygen-saturated benzene and bubbling oxygen through the mixture during the reaction. The nmr spectrum of the crude product showed Ia (22%), VIa (14%), and IIa (64%). Errors in the integration are relatively large ( $\pm 10\%$ ), but it is clear that continuous saturation of the solution with oxygen does not quench the reaction.

The procedure used was adapted from that of Brown and

(37) The apparent splitting probably is not a true coupling constant.

**Irradiation of 1-Methoxycycloheptatriene in the Presence and Absence of Oxygen.** A solution of 1-methoxycycloheptatriene (500 mg) in oxygen-free benzene (250 ml) was irradiated with a Pyrex-jacketed Hanovia immersion lamp (Type A) for 1 hr. A 50-ml aliquot of this solution was taken, and the solvent was removed. Examination of the residual oil by nmr showed Ia (21%), VIa (55%), and IIa (24%).

The same scale experiment was repeated using oxygen-saturated benzene (oxygen was bubbled through the solution throughout the period of irradiation). After 1-hr irradiation, nmr analysis showed Ia (19%), VIa (59%), and IIa (22%).

**Irradiation of 7-Methoxycycloheptatriene in the Presence and Absence of Acetophenone.** A solution of 100 mg (0.0082 mole) of 7-methoxycycloheptatriene in 5 ml of oxygen-free benzene was prepared. This solution (1 ml) was placed in each of two Pyrex nmr tubes. To one of the tubes 30 mg of acetophenone was added, then both were sealed. The tubes were irradiated with a Pyrex-jacketed Hanovia immersion lamp (Type A) through a 2-mm-thick layer of filter solution (described above). At appropriate intervals the tubes were removed, and the nmr spectra were run. After 12-hr irradiation no significant reaction had occurred in either tube.

**Irradiation of 1-Methoxycycloheptatriene in the Presence and Absence of Sensitizers.** These irradiations were carried out using nmr tubes as described above. However, in this case, after 1-hr irradiation ca. 50% of the 1-methoxycycloheptatriene had rearranged to a mixture of 7-methoxycycloheptatriene and 1-methoxybicyclo[3.2.0]hepta-3,6-diene. Addition of 1 molar equiv of acetophenone definitely slowed down the rearrangement while a 10 molar equiv excess of acetophenone effectively halted the rearrangement as did 1 equiv of benzophenone. At the concentrations used (0.16 M in substrate and sensitizer) 1-methoxycycloheptatriene ( $\epsilon_{3600}$  4.1) had a slightly higher absorbance (0.65 at 3600 Å) than acetophenone [ $\epsilon_{3600}$  3.1;  $A(0.16 M) = 0.49$ ]. Using 0.16 M 1-methoxycycloheptatriene and 1.6 M acetophenone, the respective absorbances were 0.65 and 4.90. In this case >88% of the incident light is absorbed by the acetophenone. No reaction could be detected after 1-hr irradiation. Benzene absorption is not a problem ( $\epsilon_{2400}$   $4.44 \times 10^{-4}$ ;  $\epsilon_{3600} \approx 0$ ).

## The Mechanism of Isotopic Exchange between Arylmercuric Compounds and Elemental Mercury<sup>1a</sup>

Maurice M. Kreevoy<sup>1b</sup> and Edward A. Walters<sup>1c</sup>

Contribution from the Department of Chemistry, University of Minnesota, Minneapolis, Minnesota 55455. Received December 12, 1966

**Abstract:** The mechanism of the facile isotope exchange between arylmercuric compounds in solution and metallic mercury was examined. All reasonable mechanisms except a true isotopic exchange at the surface of the liquid are eliminated. The reaction rate is not significantly limited by mass transport in either phase. The reaction shows a real but small solvent dependence which is not correlated with the solubility of the substrate or any common solvent parameter. This and the value of  $\Delta S^\ddagger$  favor a rate-determining chemisorption step. The efficiency of substrate collisions with the metal is much higher than that of collisions with the Hg<sup>0</sup> atoms in solution for bringing about exchange, suggesting a rate-determining electron transfer. Reactivity seems to be in the order  $RHgI > RHgBr > RHgCl > RHgOAc \gg RHgR$ . An over-all mechanism is proposed.

Several years ago Reutov and Ostapchuk<sup>2</sup> reported that the isotope exchange shown in eq 1, rather surprisingly, proceeded under mild conditions in a variety of solvents. Halogen atoms, aryl groups, and

certain special alkyl groups can be used as  $R_1$  and  $R_2$ .<sup>2-5</sup> The original report has been confirmed and extended in a series of papers by Reutov and his co-workers,<sup>3</sup> and by Pollard and Westwood.<sup>4,5</sup> The most important findings of these workers have been that the reaction could be carried out under conditions where its rate was not transport controlled, and that it was totally unaccompanied by chemical changes. In the case that  $R_1$

or  $R_2$  is optically active there is not even a loss of optical activity accompanying the exchange.<sup>3</sup> From these observations, and others, a mechanism involving a four-center transition state was deduced.

The present paper describes the exchange between *p*-methoxyphenylmercurials,  $RHgX$ , and elemental mercury. In contrast with previous work the rate of encounter of the substrate with the surface can be estimated. The surface area and conditions were more closely controllable than those of previous investigators. A much wider range of substrate concentrations was conveniently studied by labeling the organomercurial rather than the elemental mercury. The effect of solvent on reactivity and the solubility of the substrate in the same solvents were extensively studied. The effect of varying  $X$ , through the halogens and acetate, was studied. An upper limit was placed on the rate of the analogous reaction in homogeneous solution. The findings that the exchange is interfacial, largely unlimited by mass transport, and unaccompanied by chemical reactions were confirmed. Surface encounters are at least several orders of magnitude more effective than encounters with mercury atoms in solution for producing exchange. This finding, com-

Figure 1. A typical plot of  $\log(C_t - C_\infty)$  as a function of  $t$  for a homogeneous reaction; (RHgBr) was  $1.38 \times 10^{-5} M$ , and  $(Hg^0)$  was  $0.99 \times 10^{-5} M$ .

combined with the other findings, suggests that electron transfer from the substrate to the metal is rate determining for the exchange.

### Results

It can be shown<sup>6</sup> that an isotopic exchange reaction in which a given element is exchanged between two different chemical environments follows the rate law shown in eq 2 within any given experiment regardless of the mechanism of the exchange. In eq 2  $k$  is the

$$k = \frac{ab}{a+b} \frac{2.303}{t-t_0} \log \left( \frac{C_0 - C_\infty}{C_t - C_\infty} \right) \quad (2)$$

constant rate of exchange of labeled atoms between the two environments, with units of  $M \text{ sec}^{-1}$ ;  $a$  and  $b$  are the concentrations of labeled substances in the two environments;  $t_0$  is the time at which exchange was begun;  $t$ , the time at which it was interrupted;  $C_t$  is the counting rate at time  $t$ . Equation 2 is applicable to heterogeneous as well as homogeneous exchange reactions as long as the labeled atom does not accumulate significantly in the interfacial region. The disappearance of radioactivity from the labeled starting material was accurately described by eq 2, within the precision of the measurements, except where otherwise noted. Rate constants,  $k$ , were obtained by inspection from linear plots of  $\log(C_t - C_\infty)$  as a function of time. Typical examples of such plots, for homogeneous and heterogeneous reactions, are shown in Figures 1 and 2.

Equation 2 is limited to exchange reactions which are unaccompanied by any net chemical change. The absence of such change was verified, in the present system, for a  $5.4 \times 10^{-5} M$  solution of RHgBr in methanol, exchanging with a 25-g sample of liquid mercury (2.0-cm<sup>2</sup> surface area). The ultraviolet spectrum of the RHgBr solution was not detectably diminished during ten half-lives of exchange. About 2% diminution would have been clearly detectable.

**Homogeneous Solution.** Four rates were measured at 25° in homogeneous benzene solution, with initially labeled RHgBr, using analytical reagent grade benzene. (The solubility of mercury in benzene is  $1.2 \times 10^{-5} M$  at 25°.)<sup>7</sup> The half-lives were about 2 days.

(6) O. Meyers and R. J. Prestwood in "Radioactivity Applied to Chemistry," A. C. Wahl and N. A. Bonner, Ed., John Wiley and Sons, Inc., New York, N. Y., 1951, pp 9 and 34.

Figure 2. A typical plot of  $\log(C_t - C_\infty)$  as a function of  $t$  for a heterogeneous reaction; (RHgBr) was  $4.35 \times 10^{-5} M$ , and 25.0 g of  $Hg^0$  was used, giving a surface area of 2.0 cm<sup>2</sup>. The temperature was 25°.

The resultant  $k$  values are shown in Table I. The data are too scanty and imprecise to permit the establishment of a kinetic order with respect to either reagent, but if the reaction is assumed to be first order in each reagent the second-order rate constants,  $k_2$ , shown in Table I are obtained. Their average is  $0.25 \pm 0.05 M^{-1} \text{ sec}^{-1}$ .

Table I. Rate of Exchange in Homogeneous Benzene Solution

(RHgBr), 10 <sup>5</sup> M	(Hg <sup>0</sup> ), 10 <sup>5</sup> M	10 <sup>4</sup> $k$ , M <sup>-1</sup> sec <sup>-1</sup>	$k_2$ , M <sup>-1</sup> sec <sup>-1</sup>
0.69	0.69	1.3	0.27
0.69	0.82	0.8	0.15
1.03	0.82	2.2	0.27
1.38	0.99	4.4	0.33

Some of the scatter may be due to catalysis by impurities. When the same reaction was carried out in a poorer grade of solvent  $k$  was larger by a factor of about 5 at comparable concentrations. If the kinetic order is incorrect, then the true, bimolecular, rate constant would be smaller yet. For these reasons, the value of  $k_2$  given is more likely too large than too small.

Work on homogeneous solutions was not carried further because of the long half-lives and experimental difficulties involved.

**Heterogeneous Exchange.** Heterogeneous exchange experiments were carried out in a round-bottomed flask with a mechanical stirrer and openings for the addition and withdrawal of materials. It is identical with that previously described,<sup>8</sup> except that it had an indentation in the bottom of the flask to help stabilize the mercury sample and a piece of speedometer cable between the stirring motor and the stirrer to reduce vibration of the flask. This apparatus does not break up the mercury sample at the stirrer speeds used.

In the heterogeneous experiments the concentration of mercury in liquid mercury (68 g-atoms l.<sup>-1</sup>) is higher by a factor of 10<sup>5</sup> than the highest solution concentration used, and the quantity of mercury in the liquid is

Figure 3. Typical curved plot of  $\log(C_t - C_\infty)$  as a function of  $t$  at low (RHgBr). The (RHgBr) was  $6.93 \times 10^{-5} M$  in benzene; 25 g of  $Hg^0$  was used (2.0-cm<sup>2</sup> surface area) at 600 rpm and 25°. The solid line corresponds to a  $k_1$  of  $1.8 \times 10^{-5} \text{ sec}^{-1}$ .

higher by a factor of  $10^3$  than that in solution, so eq 2 reduces to eq 3, in which  $a$  is the concentration of

$$k/a = 2.303/(t - t_0) \log(C_0/C_t) \quad (3)$$

RHgX.

**Order With Respect to RHgBr.** A series of experiments was carried out with varying concentrations of RHgBr in benzene, 25.0-g samples of  $Hg^0$  (giving a 2.0-cm<sup>2</sup> surface area) at 25° and a stirring rate of 600 rpm. These were designed to test the reproducibility of the results and determine the order with respect to RHgBr. The results are shown in Table II. On repetition of an experiment without altering the apparatus reproducibility of better than 10% could usually be obtained. However, if the apparatus was disassembled and reassembled on another day, a discrepancy of almost a factor of 2 could sometimes be observed. This is exemplified by the results at  $3.31 \times 10^{-4} M$  RHgBr and  $3.82 \times 10^{-4} M$  RHgBr. Vibration of the apparatus is probably the cause of this variability. Reaction was notably faster when the apparatus was visibly vibrating. Within these limits the results in Table II are consistent with first-order behavior, and with no other simple order. The first-order rate constants,  $k_1$ , given by  $k/a$ , may show a slight, systematic, trend toward higher values at lower (RHgBr). Disregarding any drift, the average value of  $k_1$  was  $1.6 \times 10^{-5} \text{ sec}^{-1}$  with an average deviation from the mean of  $0.4 \times 10^{-5} \text{ sec}^{-1}$ .

At (RHgBr)  $< 2 \times 10^{-5} M$  curvature was increasingly apparent in plots of  $\log(C_t - C_\infty)$  as a function of  $t$ . Such a plot is shown in Figure 3. The origin of the curvature is not known, but it is probably associated with the loss of a small quantity of RHgBr from solution, significant by comparison with the very small quantities initially involved. The terminal slope of such plots gave  $k_1$  values consistent with those obtained at higher (RHgBr). The beginning of such curvature, unnoticeable at slightly higher (RHgBr), is probably responsible for the slight drift to higher values of  $k_1$  at lower (RHgBr) in Table II.

<sup>a</sup> Four experiments, with average deviation from the mean, 2%.

<sup>b</sup> Three experiments, with average deviation from the mean, 10%.

**State of Aggregation of RHgBr.** The method of differential vapor pressures<sup>9</sup> was used<sup>10</sup> to determine a van't Hoff  $i$  of 1.0 for RHgBr.

**Mercury Surface Area.** The rate was studied as a function of surface area,  $A$ , with RHgBr in benzene solution at 25°, at a stirring rate of 600 rpm. Except where noted, (RHgBr) was  $4 \times 10^{-5} M$ . The surface area was varied by varying the size of the mercury sample, and determined by measurement with calipers. In this way the surface area could be increased by a factor of more than 6. As shown in Table III,  $k_1/A$  is constant within the precision of the measurements. Variation of the sample size also changed the vertical distance between the stirrer and the mercury surface. It was independently shown that  $k_1$  was invariant under comparable changes in the distance between the surface and the stirrer at constant mercury sample size and surface area. The 25-g sample, with 2.0-cm<sup>2</sup> surface area, was adopted as standard and used throughout the rest of this work. Rate constants per unit area can be obtained by dividing those reported by 2.0.

**Stirring Rate.** The variation of  $k_1$  with stirring rate was studied for RHgBr in several solvents at 25° with 25-g mercury samples and substrate concentrations around  $4 \times 10^{-5} M$ . The results are shown in Table IV for benzene. They were similar for isooctane (2,2,4-trimethylpentane) and nitrobenzene. There is no significant variation of reaction rate with stirring rate at or above 400 rpm.

<sup>a</sup> Average of 20 determinations, taken from Table II.

**Effect of Temperature.** In order to determine the thermodynamic parameters of activation,  $k_1$  was measured for RHgBr in toluene, using a 25-g mercury sample at a 600 rpm stirring rate, at four temperatures between 1 and 40°. A total of seven determinations of  $k_1$  were made. The logarithm of  $k_1/T$  was a linear function of  $1/T$  within the precision of the measurements. Standard equations<sup>11</sup> were used to get the enthalpy of activation,  $\Delta H^\ddagger$ , by the method of least squares.<sup>12</sup> Its value, 8.1 kcal mole<sup>-1</sup>, with 50% confidence limits of 0.2 kcal mole<sup>-1</sup> and 90% confidence limits of 0.3 kcal mole<sup>-1</sup>.

The value of the entropy of activation,  $\Delta S^\ddagger$ , depends on the standard state chosen for the starting state and the transition state. For ease of interpretation a 1 mole solution in toluene has been chosen for the starting state and 1 mole cm<sup>-3</sup> for the transition state. The smoothed value of  $k_1$  at 25°,  $1.75 \times 10^{-5}$  sec<sup>-1</sup>, when multiplied by the solution volume, 0.15 l, and divided by the reactive surface area, 2 cm<sup>2</sup>, becomes  $\Delta F^\ddagger$ , the free energy of activation, can be obtained from eq 4.<sup>11</sup> In eq 4  $k_r$  is the rate constant described

$$\Delta F^\ddagger = -RT \ln (k_r h / kT) \quad (4)$$

where  $h$  is Planck's constant, with a value of  $1.3 \times 10^{-6}$  l. sec<sup>-1</sup> cm<sup>-3</sup> at 25° in toluene, and the other quantities are the usual physical constants. This leads to a value of 25.5 kcal

M. M. Kreevoy in "Investigation of Rates and Mechanisms of Chemical Reactions," S. L. Friess, E. S. Lewis, and A. Weissberger, Eds., Interscience Publishers, Inc., New York, N. Y., 1963, p 1392.

C. A. Bennett and N. L. Franklin, "Statistical Analysis in Chemistry and the Chemical Industry," John Wiley and Sons, Inc., New York, 1954, pp 36-40.

mole<sup>-1</sup> for  $\Delta F^\ddagger$ , and, via the usual thermodynamic equalities,<sup>11</sup> to a value of  $-58.4$  cal mole<sup>-1</sup> deg<sup>-1</sup> for  $\Delta S^\ddagger$ , with 50% confidence limits of 0.7 cal mole<sup>-1</sup> deg<sup>-1</sup>.

**Inhibition and Catalysis.** A number of substances were tested for catalytic or inhibitory effects. For the most part these were substances known to or expected to adsorb on a mercury surface, or to complex the substrate. These experiments were carried out with RHgBr as the substrate, a 600-rpm stirring rate, and a 25-g mercury sample. In methanol as a solvent,  $4 \times 10^{-1}$  M sodium bromide and  $1.4 \times 10^{-1}$  M hydroquinone were without measureable effect. In benzene as a solvent, silicone grease and  $6 \times 10^{-4}$  M *p*-bromoanisole were without effect. However,  $4 \times 10^{-4}$  M stearic acid retarded the rate in benzene by a factor of about 2;  $1.4 \times 10^{-6}$  M HgBr<sub>2</sub> and also  $2.6 \times 10^{-6}$  M HgBr<sub>2</sub> accelerated it by about the same factor, both by comparison with a standard  $k_1$  of  $1.6 \times 10^{-5}$  sec<sup>-1</sup>. These changes appear to be outside of the scatter shown in Table II, although not far outside.

**Reaction of HgBr<sub>2</sub> with Mercury.** Mercuric bromide in solution reacts with liquid mercury, giving solid Hg<sub>2</sub>Br<sub>2</sub>. In isooctane, the ultraviolet spectrum of residual HgBr<sub>2</sub> can be detected, but no evidence of Hg<sub>2</sub>Br<sub>2</sub> can be found in solution, so the equilibrium can be formulated as shown in eq 5. Using <sup>203</sup>Hg as a

tracer, and assuming that all the mercury in solution was in the form of HgBr<sub>2</sub>, the equilibrium constant  $K_5$  was measured for benzene solutions. Five determinations were made: two starting with solutions of HgBr<sub>2</sub>, liquid mercury, and no Hg<sub>2</sub>Br<sub>2</sub>, and three starting with liquid mercury, freshly precipitated Hg<sub>2</sub>Br<sub>2</sub>, solvent, and no HgBr<sub>2</sub>. The average value of  $K_5$  was  $2.5 \times 10^6$  M<sup>-1</sup>, with an average deviation from the mean of  $0.5 \times 10^6$  M<sup>-1</sup>, and no systematic difference between those run forward and those run backward.

The experiments to test the catalytic effectiveness of HgBr<sub>2</sub> were carried out at concentrations well below the equilibrium concentration of HgBr<sub>2</sub>,  $4 \times 10^{-6}$  M, so that no Hg<sub>2</sub>Br<sub>2</sub> should have been present at equilibrium. Nevertheless, a few minutes after the reaction was begun, a precipitate of Hg<sub>2</sub>Br<sub>2</sub> appeared at the metallic surface. After about 1 hr, the precipitate redissolved, so that, at equilibrium, the conditions of equilibrium were satisfied. The exchange reaction (eq 1) was proceeding all during the precipitation and resolution, but its rate was not detectably affected by these phenomena. This whole group of observations undoubtedly deserves, and will receive, further attention.

**Disproportionation.** An attempt was made to determine the equilibrium constant  $K_6$  for the reaction shown in eq 6. It was determined (by spectrophotom-

etry in the presence of 0.1 M NaI) that water in equilibrium with  $8.2 \times 10^{-4}$  M RHgBr contained less than  $10^{-6}$  M of HgBr<sub>2</sub>. Since the distribution constant of HgBr<sub>2</sub> between water and benzene is 0.90 (favoring benzene)<sup>13</sup> an upper limit of  $1.8 \times 10^{-6}$  can be set for  $K_6$ .

(13) M. S. Sherrill, *Z. Physik. Chem.*, **43**, 705 (1903).

**Solubility.** The solubility,  $S$ , of  $\text{RHgBr}$  in all the solvents used for rate measurements was determined at  $25^\circ$ . Each measurement was made at least once from each direction, *i.e.*, by saturating an initially unsaturated solution with excess solid, and by allowing an initially supersaturated solution to equilibrate with the solid. The concentration of the equilibrated solutions was determined spectrophotometrically in methanol, by means of their radioactivity, using labeled  $\text{RHgBr}$  in the other solvents. Both methods were used for isooctane, and were in good agreement. The results are shown in Table VI.

Table VI. Solubility of  $\text{RHgBr}$  at  $25^\circ$

Solvent	$S, M$
Water	$1.4 \times 10^{-4}$
Isooctane	$5.1 \times 10^{-4}$ <sup>a</sup>
Isooctane	$5.2 \times 10^{-4}$ <sup>b</sup>
Methanol	$2.3 \times 10^{-3}$
Toluene	$3.5 \times 10^{-3}$
Benzene	$5.6 \times 10^{-3}$
Hexamethylphosphoramide	$6.2 \times 10^{-3}$
Anisole	$8.9 \times 10^{-3}$
Nitrobenzene	$1.8 \times 10^{-3}$
Acetone	$1.9 \times 10^{-3}$

<sup>a</sup> Measured spectrophotometrically. <sup>b</sup> Measured by means of radioactivity.

In addition, 12 determinations of  $S$  in toluene were made at a series of temperatures between  $0$  and  $55^\circ$ . A plot of  $\log S$  as a function of  $1/T$  was linear, within the scatter of the measurements. From these data, using the van't Hoff equation<sup>14</sup> and the method of least squares,<sup>12</sup> the standard enthalpy of solution,  $\Delta H^\circ$ , is  $4.9 \text{ kcal mole}^{-1}$ , with 50% confidence limits of  $\pm 0.15 \text{ kcal mole}^{-1}$ . Properly, this pertains to the midpoint of the temperature range studied,  $27.5^\circ$ . Using the standard equations, the entropy of solution,  $\Delta S^\circ$ , is  $5.1 \pm 0.5 \text{ cal mole}^{-1} \text{ deg}^{-1}$  if an ideal,  $1 M$ , solution is chosen as standard state for  $\text{RHgBr}(\text{soln})$  and the solid itself is the standard state for  $\text{RHgBr}(\text{s})$ .

## Discussion

The present work supports the earlier conclusion<sup>2-5</sup> that the rate of the exchange reaction, eq 1, is not, generally, mass transport controlled. For the fastest exchanging compounds, in the most activating solvents, however, mass transport in the solution phase may play a role. For example,  $\text{RHgI}$  in isooctane exchanges with a rate constant almost half that for mercury reprecipitation under similar conditions<sup>8</sup> after correction for the difference in surface area. The latter reaction is thought to be mass transport controlled,<sup>8</sup> and it has been shown that the diffusion coefficient of atomic mercury in isooctane is not strikingly different from those of other species.<sup>15</sup> Most of the other exchange reactions were substantially slower than that of  $\text{RHgI}$  in isooctane, however, so the mass transport process must be relatively unimportant in determining their rates. This conclusion is supported by the substantial variation in exchange rate with substrate structure and by the invariance of the exchange rate with the stirring

rate. In addition,  $\Delta H^\ddagger$  for exchange in toluene is  $\sim 5 \text{ kcal mole}^{-1}$  larger than would be expected for a transport-controlled reaction.<sup>16</sup>

The diffusion of radioactive mercury away from the interface seems totally unimportant in determining the exchange rate. This is shown by the linear plots of  $\log C_i$  as a function of  $t$ ,<sup>6</sup> by the variation of rate as a function of  $X$  and solvent, and by a calculation of the concentration of labeled mercury at the interface during an exchange. In this calculation it was assumed that a concentration of labeled mercury atoms,  $C_{\text{Hg}^*}$ , was continuously maintained by the exchange at the surface of a cylindrical well of mercury. (This is the condition that would prevail if the exchange rate were controlled by diffusion in the mercury.) Standard equations<sup>17</sup> and the known self-diffusion coefficient of mercury<sup>18</sup> were then used to calculate the concentration of labeled mercury,  $C_{\text{Hg}^*}$ , as a function of  $C_{\text{Hg}^*}$  and the distance from the surface, at a time comparable to a half-life for exchange. The area under this curve was equated to the quantity of labeled mercury deposited from the most concentrated reaction mixture in a half-life. This gave a value for the only variable,  $C_{\text{Hg}^*}$ . It was  $3 \times 10^{-3} M$ , which can be compared with a total mercury concentration of  $68 M$  in  $\text{Hg}^0(\text{l})$ .

An exchange mechanism involving  $\text{HgX}_2$ , shown in eq 7 and 8, has been discounted by Reutov.<sup>3</sup> The pres-

ent results on disproportionation rigorously disallow it as the major exchange path. These set an upper limit of  $10^{-6} M$  on the concentration of  $\text{HgBr}_2$  in equilibrium with  $8.2 \times 10^{-4} M$   $\text{RHgBr}$  in benzene at  $25^\circ$ . Assuming the mercury reprecipitation and the reaction shown in eq 8 are mass transport limited they would both have first-order rate constants of  $3.2 \times 10^{-4} \text{ sec}^{-1}$ .<sup>8</sup> This leads to an exchange rate of  $3.2 \times 10^{-10} \text{ g-atom sec}^{-1}$ , and an apparent first-order rate constant for  $\text{RHgBr}$  exchange of  $4 \times 10^{-7} \text{ sec}^{-1}$ . This is only 2.5% of the observed rate constant under these conditions,  $1.6 \times 10^{-6} \text{ sec}^{-1}$ . Even when the  $\text{HgBr}_2$  concentration is increased by deliberate addition, the reactions shown in eq 7 and 8 cannot account for as much as 10% of the observed  $k_1$ , so they cannot even account for the apparent catalysis by added  $\text{HgBr}_2$ . Entirely similar reasoning excludes significant contributions to the overall exchange from the reactions shown in eq 9 and 10.

The foregoing excludes all of the reasonable mechanisms for exchange except those involving the direct interaction of  $\text{RHgX}$  with the surface. A generalized scheme for a surface mechanism is shown in eq 11-13.

In those equations,  $\text{RHg}^*\text{X}(\text{surf.})$  represents unreacted

ate in contact with the surface and  $\text{RHg}^+\text{X}^-$ ·Hg enters chemisorbed but unexchanged substrate. 13 represents the rate-determining step,  $k_1$  is given  $\propto K_{12} \propto K_{11}$ , where  $k$  is a rate constant,  $K$  is an equilibrium constant, and the subscript gives the equation to which the constant pertains. There should be solvent specificity for  $K_{11}$  and not very much for  $K_{12}$  since it pertains to a reaction of a chemisorbed species, rather than one in solution. On the other hand, it could approximate inverse proportionality with  $S$  if it pertains to a process that removes  $\text{RHgBr}$  from solution. This suggests that  $k_1$  should show an approximate inverse proportionality with  $S$ . Comparison of Tables V and VI reveals little correlation between  $k_1$  and  $S$ . Reutov and Ostapchuk<sup>2</sup> have indicated that the rate is independent of solvent. While variation in  $k_1$  with solvent is unquestionably real, considerably smaller than the variation in  $S$ . These observations make it unlikely that the reaction in eq 13 is rate determining. It has already been shown that mass transport, eq 11, is not rate determining. This leaves only the chemisorption step, eq 12, as the attractive rate-determining step. The present previous<sup>2-5</sup> results are entirely compatible with the hypothesis provided that the transition state resembles the starting state.

Substituent effects on reactivity reported by Pollard and Westwood<sup>5</sup> indicate that the aromatic fragment becomes somewhat electron deficient in the transition state, but the effects are small. Pollard and Westwood report a Hammett  $\rho$  of  $-1$  for substitution by aryl groups. Values between 2 and 3 are commonly observed for generation of unit charge on an atom directly attached to the ring,<sup>19</sup> and since there are substituted benzene rings in the present case, an larger effect might be expected if unit charge were developed. The present results could be taken to indicate development of an electron deficiency on mercury in the transition state, as the rate increases steadily decreasing electronegativity. However, such a conclusion would imply that di-*p*-anisylmercury ( $\text{R}$ ) should react faster than  $\text{RHgI}$ . In fact it has a rate constant which extrapolates to  $3.6 \times 10^{-10}$  l.  $\text{sec}^{-1}$  at  $25^\circ$  in benzene.<sup>5</sup> This is slower by some powers of 10 than  $\text{RHgOAc}$  and slower by a factor of 10 than  $\text{RHgI}$ . The observation that  $\text{RHgR}$  reacts more slowly than  $\text{RHgCl}$  also seems to contradict the postulate<sup>5</sup> that the rate-determining step for the reaction resembles that for electrophilic substitution. Electrophilic substitution by  $\text{H}^+$  is much faster with arylmercury than with phenylmercuric chloride, and the latter is the product of the reaction of di-mercury with dilute methanolic  $\text{HCl}$ .<sup>20</sup>

Very small changes accompanying changes in  $S$  and the slow reactions in hexamethylphosphoramide suggest complete ionization in that solvent, possibly with the formation of ion pairs,  $\text{RHg}^+(\text{nt})^+\text{X}^-$ .

The  $\Delta S^\ddagger$  values reported by Pollard and Westwood<sup>5</sup> calculated for standard states of an ideal, 1  $M$  solution for the starting state and 1 mole  $\text{cm}^{-3}$  for the transition state they give values (except for dibenzyl-

G. B. Barlin and D. D. Perrin, *Quart. Rev. (London)*, **20**, 75 (1966); H. Zimmer and S. Makower, *Naturwissenschaften*, **23**, 551

mercury) quite close to that reported here. Diphenylmercury, for example, gives  $-57$  cal  $\text{mole}^{-1}$   $\text{deg}^{-1}$ . (The original values appear to refer to a standard state of 1 mole/20 ml for the starting state and 1 mole/1000  $\text{cm}^3$  for the transition state.) Thus the differences in reactivity commented on above are probably due, in largest part, to changes in  $\Delta H^\ddagger$ .

If the changes in the entropy of solvation and the entropy of the metal accompanying the activation process can be neglected, the observed  $\Delta S^\ddagger$  values are consistent with a transition state in which one translational degree of freedom has become the reaction coordinate. With standard states of 1 mole  $\text{cm}^{-3}$  for the starting state and 1 mole  $\text{cm}^{-2}$  for the transition state, the loss of one degree of translational freedom in the latter leads to the entropy shown in eq 14 for a

$$\Delta S^\ddagger = -R \ln (2\pi mkT_e)^{1/2}/h \quad (14)$$

gas.<sup>21</sup> The symbols have their usual significance. The value of  $\Delta S^\ddagger$  computed is  $-41.6$  cal  $\text{mole}^{-1}$   $\text{deg}^{-1}$ . The use of 1  $M$  as the standard state for the starting material adds another  $-R \ln 10^3$ , so that the final calculated value is  $-55.3$  cal  $\text{mole}^{-1}$   $\text{deg}^{-1}$ . The very good numerical agreement between this and the experimental value ( $-58.4 \pm 0.7$  cal  $\text{mole}^{-1}$   $\text{deg}^{-1}$ ) is fortuitous. The calculated value would probably be 1–5 cal  $\text{mole}^{-1}$   $\text{deg}^{-1}$  smaller if a proper calculation could be made for the solution.<sup>22</sup> Nevertheless the agreement does strongly suggest that considerable translational freedom parallel to the surface is retained by the transition state. If this were lost, a much more negative value would be obtained ( $< -100$  cal  $\text{mole}^{-1}$   $\text{deg}^{-1}$ ).<sup>21</sup>

Previous workers<sup>2-5</sup> have favored a four-center, over-all transition state, 1, for this reaction, without specifying

whether this stage is reached during the chemisorption or subsequent steps. It now seems unlikely that 1 could be the over-all transition state for the reaction. The strongest argument against it is the relative efficiency of the surface reaction as compared to the homogeneous solution reaction. The simplest models<sup>23</sup> for collisions in solutions give collision rate constants

(21) S. Glasstone, K. J. Laidler, and H. Eyring, "The Theory of Rate Processes," McGraw-Hill Book Co., Inc., New York, N. Y., 1951, p 398.

(22) The translational entropy in solution is less than that in the gas phase by about 3 cal  $\text{mole}^{-1}$   $\text{deg}^{-1}$  for a molecule of about this molecular weight which does not interact specifically with the solvent. For example, the entropy of solution of  $\text{I}_2$  vapor in isooctane is  $-3.2$  cal  $\text{mole}^{-1}$   $\text{deg}^{-1}$  [J. H. Hildebrand and D. N. Glew, *J. Phys. Chem.*, **60**, 618 (1956)]. Thus, the loss of one degree of translational freedom for such a molecule would lead to an entropy contribution about 1 cal  $\text{mole}^{-1}$   $\text{deg}^{-1}$  less negative than a similar loss from the gas phase. However, the entropy of solution of  $\text{RHgBr}$  vapor in toluene would be more negative than that of  $\text{I}_2$  in isooctane because its entropy of solution from the solid, 5 cal  $\text{mole}^{-1}$   $\text{deg}^{-1}$ , is less positive than the entropy of solution of solids which give noninteracting solutions. For example, naphthalene, biphenyl, and diphenylamine all give entropies of solution in benzene of 17–18 cal  $\text{mole}^{-1}$   $\text{deg}^{-1}$  [H. Stephen and T. Stephen, "Solubilities of Inorganic and Organic Compounds," The Macmillan Co., New York, N. Y., 1963, pp 1434, 1436, and 1552; K. Suzuki and S. Seki, *Bull. Chem. Soc. Japan*, **28**, 417 (1955); G. Gehlhoff, *Z. Physik. Chem.*, **98**, 252 (1921)]. The exact effect of this on  $\Delta S^\ddagger$  is impossible to evaluate but 5 cal  $\text{mole}^{-1}$   $\text{deg}^{-1}$  seems like a reasonable upper limit.

(23) E. A. Moelwyn-Hughes, "The Kinetics of Reactions in Solution," Oxford at the Clarendon Press, London, 1947, pp 8–9.

of  $33 \text{ l. sec}^{-1} \text{ cm}^{-2}$  for a surface and  $\sim 10^{11} \text{ M}^{-1} \text{ sec}^{-1}$  for bimolecular collisions in solution. The pertinent observed rate constants in benzene are  $1.2 \times 10^{-8} \text{ l. sec}^{-1} \text{ cm}^{-2}$  for the surface reaction and  $0.25 \text{ M}^{-1} \text{ sec}^{-1}$  in solution, so the fraction of successful conversions in the former case is  $4 \times 10^{-8}$ , and, in the latter,  $3 \times 10^{-12}$ . More sophisticated treatment of the collision frequencies<sup>24</sup> may substantially alter these numerical values, but the conclusion that the surface reaction is much more efficient is not altered unless the substrate is attracted to the surface in strong preference to the solvent. Considering the solvent structures represented in Table V, this seems quite unlikely. It is hard to see why a transition state like 1 should be more easily formed from liquid mercury than from a mercury atom in solution. The former would seem to require most of the energy necessary to abstract a mercury atom from the liquid ( $8 \text{ kcal mole}^{-1}$ ) in addition to most of the energy required by the latter.

It is also hard to see how 1 could be compatible with the requirement that the transition state retains its mobility parallel to the surface, as suggested by  $\Delta S^\ddagger$ .

A rate-determining step that is consistent with all the evidence is electron transfer from the substrate to the mercury. This would account for the particular effectiveness of the metal, since its electron affinity must be essentially the same as its work function,  $105 \text{ kcal mole}^{-1}$ ,<sup>25</sup> while that of atomic mercury is  $30\text{--}40 \text{ kcal mole}^{-1}$ .<sup>26</sup> There is no definitive experimental evidence excluding 1 as a transition state for a fast exchange step following the chemisorption step, but there is also no evidence strongly supporting it. We prefer the mechanism shown in eq 15–18 because of its analogy with the reversible formation of the mercurous halides at a mercury surface. A definitive conclusion will

have to depend on further experimental results.

## Experimental Section

**Materials.** The general scheme by which the various radioactive mercury compounds were prepared is shown.

Bis(*p*-methoxyphenyl)borinic acid was prepared in 27% yield by the method of Hawthorne.<sup>27</sup> It had mp  $102\text{--}105^\circ$  (lit.<sup>27</sup>  $107^\circ$ ).

The two *p*-methoxyphenylmercuric halides were prepared by the method of Torsell<sup>28</sup> from the borinic acid and the appropriate mercuric halide. The latter were labeled simply by mixing them in solution with small amounts of labeled  $\text{Hg}(\text{NO}_3)_2$  in aqueous  $\text{HNO}_3$ , which is the form in which the  $^{203}\text{Hg}$  was obtained. The labeled chloride was obtained in 95% yield and had mp  $251.0\text{--}251.5^\circ$ , in a sealed, evacuated capillary (lit.<sup>28</sup>  $249\text{--}250^\circ$ ). The bromide was obtained in 44% yield and had mp  $255\text{--}256^\circ$ , in a sealed, evacuated capillary (lit.<sup>28</sup>  $255\text{--}256^\circ$ ).

To obtain *p*-methoxyphenylmercuric acetate  $0.31 \text{ g}$  ( $9 \times 10^{-4} \text{ mole}$ ) of the labeled chloride in  $60 \text{ ml}$  of hot benzene was treated with  $0.14 \text{ g}$  ( $8.5 \times 10^{-4} \text{ mole}$ ) of silver acetate in  $80 \text{ ml}$  of ethanol (containing just enough water to give a clear solution). A precipitate formed immediately. The reaction mixture was refluxed gently for 15 min to coagulate the precipitate, which was then filtered. The solvent was removed from the filtrate under vacuum. The residual solid was recrystallized from ethyl acetate to give  $0.18 \text{ g}$  of product ( $4.9 \times 10^{-4} \text{ mole}$ , 54% yield), mp  $179.5\text{--}180.5^\circ$ , in a sealed, evacuated capillary (lit.<sup>29</sup>  $178\text{--}179^\circ$ ).

To obtain the iodide,  $0.52 \text{ g}$  ( $1.5 \times 10^{-3} \text{ mole}$ ) of the radioactive chloride was dissolved in  $200 \text{ ml}$  of benzene and shaken with four  $25\text{-ml}$  portions of a 50% (by weight) solution of potassium iodide in water. The benzene layer was then separated and dried over magnesium sulfate. The solvent was removed under vacuum and the product recrystallized from  $30 \text{ ml}$  of ethyl acetate to give  $0.30 \text{ g}$  ( $0.7 \text{ mole}$ , 45% yield) of labeled *p*-methoxyphenylmercuric iodide, mp  $237\text{--}238^\circ$  in a sealed, evacuated capillary (lit.<sup>30</sup>  $237.8\text{--}238.1^\circ$ ).

The benzene, carbon tetrachloride, and isooctane used in kinetic and solubility studies were of spectrograde quality. The first two were obtained from Mallinckrodt Chemical Works, Inc., the latter from Phillips Petroleum Co. Hexamethylphosphoramide was obtained from Aldrich Chemical Co., and was their best grade. All of these were used without further purification. Methanol was obtained from E. I. duPont de Nemours, & Co., Inc., anisole from Aldrich Chemical Co., nitrobenzene, acetone, and toluene from Eastman Kodak Co., and all were purified by distillation. Triply distilled mercury was used.

**Kinetic Procedures.** The homogeneous kinetic experiments were initiated by adding a small quantity of a stock solution of  $\text{RHg}^+\text{Br}$  to a solution of  $\text{Hg}^0$ . The mixture was held at constant temperature in a thermostat and  $10\text{-ml}$  aliquots were removed periodically. Nitrogen gas was bubbled through these vigorously for 5 min, then vapor was passed through a sulfur tower and then into a fume hood. This treatment codistilled about half of the solvent and all of the mercury. In a control experiment, this was several times the length of time necessary to remove all the  $\text{Hg}^0$  from a saturated solution in isooctane, as judged by the ultraviolet spectrum. The volume of the demercurated aliquot was then restored to  $10 \text{ ml}$ , and the radioactivity in half of it was determined with a Nuclear-Chicago DS 5-5 well-type scintillation counter with a thallium-activated sodium iodide crystal detector. A Nuclear-Chicago Model 186 scalar equipped with an automatic timer was used to accumulate a total of at least 10,000 counts. No experiments were carried out in which the initial radioactivity was less than ten times background.

The technique for measuring heterogeneous rates was very similar to that used to measure the rate of reaction of mercury with iodine, except that the radioactivity of the samples was determined, as described above, instead of analyzing them spectrophotometrically.

**Solubility Measurements.** For solvents transparent in the ultraviolet, a subsaturated solution of known concentration was prepared and its spectrum determined. This was compared with the spectrum of the saturated solutions to determine their concentration. The saturated solutions were diluted as necessary. For opaque solvents the radioactivity of a solution of known concentration was determined, then the radioactivity of a saturated solution. In each solvent and at each temperature, saturation was approached from both sides; both pure solvent and supersaturated solutions were equilibrated with the crystals. Supersaturated solutions were obtained at higher temperatures. The equilibration was achieved by magnetically stirring a closed flask containing the solution and the crystals at constant temperature until no further change took place.

# Stable Carbonium Ions. XXXIII.<sup>1a</sup>

## Primary Alkoxy-carbonium Ions

George A. Olah and J. Martin Bollinger<sup>1b</sup>

Contribution from the Department of Chemistry, Case Western Reserve University, Cleveland, Ohio 44106. Received January 21, 1967

**Abstract:** Several primary alkoxy- and alkoxyhalocarbonium ions were directly observed by nmr spectroscopy in the solvent system antimony pentafluoride-sulfur dioxide. Methoxychloro- and methoxyfluorocarbonium ions were found to exist in isomeric forms indicating a rotational barrier around the C-O bond. In the nmr spectra of methoxy- and chloromethoxycarbonium ions nonequivalence of the methylene protons was not observed. Chloromethoxycarbonium ion exhibited a temperature-dependent spectrum because of intermolecular exchange.

Primary and tertiary alkoxy-carbonium ions were prepared by Meerwein, *et al.*,<sup>2</sup> by alkylation of esters, and lactones with trimethyloxonium or trimethyloxonium tetrafluoroborate or by abstraction of a methyl group from acetals and orthoesters. Recently Ramsey and Taft,<sup>3</sup> Hart and Tomalia,<sup>4</sup> and Heinrich,<sup>5</sup> and Kabuss<sup>6</sup> reported on the observation (nmr) or isolation of a series of additional secondary and tertiary alkoxy-carbonium ions. We would like to report now our results relating to the observation of stable primary alkoxy- and haloalkoxy-carbonium ions. No primary alkoxy-carbonium ion is known from the literature. The only other long-lived primary carbonium ions reported are methoxycarbonium ions.<sup>7</sup>

### Experimental Discussion

Methoxycarbonium ion is dissolved in antimony pentafluoride diluted with sulfur dioxide, a clear solution is obtained. The pmr spectrum of the solution at  $-60^\circ$  (Figure 1) clearly indicates the formation of the methoxycarbonium ion (I).

The nature of I was deduced from the following observations. (1) The pmr spectrum shows deshielding of both the methylene ( $\delta = -9.94$  ppm) and methoxy ( $\delta = -5.66$  ppm) protons. (2) The large coupling, giving rise to a triplet and a doublet, indicates formation of an  $\text{sp}^2$  center. (3) Analysis of the solution of I gave a high yield of methanol.

Ion I could also be observed to arise from the decarboxylation of the methoxyacetyl cation [methoxymethyloxocarbonium ion (II)] which is formed when methoxyacetyl chloride (fluoride) is treated with antimony pentafluoride in sulfur dioxide solution.

If a solution of II is maintained at  $-60^\circ$  decarbonylation is very slow and the pmr spectrum of the oxocarbonium ion is observed. Near  $-20^\circ$  decarbonylation is very fast and ion I is quantitatively generated.

We had anticipated that in ion I the positive charge will be substantially located on oxygen and therefore a high rotational (inversional) barrier would exist about the methylene-oxygen bond (Ia). Ramsey and Taft<sup>3</sup>

reported an activation energy of nearly 11 kcal/mole for the coalescence of the two nonequivalent methoxyl groups in the dimethoxymethylcarbonium ion,  $(\text{CH}_3\text{O})_2\text{C}^+\text{CH}_3$ . However, the same authors found only line broadening but not separation, indicative of an observable rotational barrier, in the triethoxy-, dimethoxy-, and diethoxycarbonium ions.

The multiplicity of the absorptions observed for the methoxycarbonium ion, *i.e.*, a quartet and a triplet, would seem to indicate that this ion is freely rotating. This appears unreasonable in view of the 11-kcal activation energy measured by Taft and Ramsey<sup>3</sup> for coalescence of the two nonequivalent methoxy groups in dimethoxymethylcarbonium ion and the *cis-trans* isomerism observed by us for the halomethoxycarbonium ions (subsequent discussion). One would anticipate a considerably larger activation energy for rotation in a primary alkoxy-carbonium ion than in a tertiary one. We therefore suggest that the spectrum observed for the methoxycarbonium ion corresponds to an AA'X<sub>2</sub> spectrum which is deceptively simple and that the observed coupling is an average of the *cis*

Figure 1.

Figure 2.

and *trans* allylic couplings. This interpretation requires that the methyl group and the lone electron pair (see 1a) have the same effect on their respective nearest

Figure 3.

protons causing the same chemical shift for these two methylene protons.

Similar considerations also apply to chloromethoxycarbonium ion. Bis(chloromethyl) ether in  $\text{SbF}_5\text{-SO}_2$  solution is ionized to form the chloromethoxycarbonium ion III. The pmr spectrum of III (Figure 4) at  $-80^\circ$

consists of two triplets at  $-9.82$  and  $-6.76$  ppm,  $J_{\text{H-H}} = 1.2$  Hz. This ion is very sensitive to the manner of preparation, and a temperature-dependent spectrum can readily be obtained. This effect is illustrated in Figure 5 showing the coalescence of the  $\text{CH}_2\text{Cl}$  and  $\text{CH}_2$  peaks on raising the temperature. Coalescence was also observed simply by adding a small amount of additional bis(chloromethyl) ether. This indicates that in ion III intermolecular exchange may take place (between ion III and un-ionized bis[chloromethyl] ether). Our data do not, however, rule out intramolecular exchange.

It should be mentioned, as in the case of ion I, that there is no noticeable nonequivalence of the methylene protons of ion III. Thus there is not an observable barrier to rotation in the oxonium form of III and IV, although again we believe this to be a result of coincidental chemical shifts and deceptive simplicity.

When  $\alpha,\alpha$ -dichloromethyl ether is dissolved in  $\text{SbF}_5\text{-SO}_2$  at  $-60^\circ$ , the pmr spectrum (Figure 2) indicates

Figure 4.

formation of the methoxychlorocarbonium ion. This ion exists in two conformational forms 'a and b, of which 81% is IVa and 19% is IVb (mea-

red by integration of the pmr spectrum). This assignment is made on the basis of the larger coupling expected for a *cis* allylic coupling.<sup>8</sup> (We found  $J = 1.2$  Hz for the *cis* allylic coupling in IVa and  $J = 7$  Hz for the *trans* allylic coupling in IVb). No change in the relative amounts of the two species was found between  $-40$  and  $-90^\circ$ .

This interpretation is supported by observation of the ethoxyfluorocarbonium ion V prepared by ionization of  $\alpha,\alpha$ -difluoromethyl methyl ether<sup>9</sup> in antimony pentafluoride-sulfur dioxide solution.

The pmr spectrum of V at  $-40^\circ$  (the ion was poorly soluble at lower temperatures; near  $-20^\circ$  it decomposed with gas evolution), shown in Figure 3, is

(8) S. Sternbell, *Rev. Pure Appl. Chem.*, **14**, 15 (1964).

Figure 5.

again a composite of 70% Va and 30% Vb (by integration of both the proton and the fluorine spectra). Again, on the basis of the larger coupling found in Va, this species is assigned the *cis* allylic proton conformation. It is of interest that the fluorine atom does not show detectable coupling with the methoxy group in Va. However, the methoxy group of Vb on expanded sweep width can be seen to be a triplet with 0.7-Hz separations. In this conformation the fluorine atom couples with the methoxy group with the same value as the hydrogen atom. The geminal H-F coupling in both conformations is 98 Hz and provides support for the  $sp^2$  nature of the carbon atom,<sup>10</sup> as do the large downfield shifts of the fluorine atoms observed for both species ( $\text{CF}_2\text{HOCH}_3$  appears as a doublet,  $J_{\text{H-F}} = 75$  Hz, at  $+89.7$  ppm; Va appears as a doublet,  $J_{\text{H-F}}^{\text{me}} = 98$  Hz, at  $-49.9$  ppm and Vb appears as a doublet further split into quartets,  $J_{\text{H-F}}^{\text{me}} = 98$  Hz,  $J_{\text{H-F}}^{\text{allylic}} = 0.7$  Hz, at  $-41.8$  ppm, all from external  $\text{FCCl}_3$  at  $-40^\circ$ ).

Observations of *cis-trans* isomerism in the halomethoxycarbonium ion shows that structures such as Ia, IVa and b, Va and b, etc., are obviously the important contributing resonance structure of alkoxy ions. On the other hand, the very substantial deshielding of the methylene protons in the methoxy- and chloromethoxycarbonium ions indicates that substantial charge is localized on the methylene carbon atom, and I and III can be considered as stable primary carbonium ions.

(10) H. M. McConnell, C. A. Reilly, and A. D. McLean, *J. Chem. Phys.*, **24**, 479 (1956), find  $J_{\text{H-F}} = 81$  Hz in 1,1-dichlorofluoroethylene. G. A. Olah and E. B. Baker (in "Friedel-Crafts and Related Reactions," Vol. III, G. A. Olah, Ed., Interscience Division of John Wiley and Sons, Inc., New York, N. Y., 1964, pp 1182-1183) found 182.5 Hz for  $J_{\text{H-F}}$  in formyl fluoride.

### Experimental Section

All of the halo ethers except  $\alpha,\alpha$ -difluoromethyl methyl ether were commercially available and used as obtained.  $\alpha,\alpha$ -Difluoromethyl methyl ether was prepared by the method of Hine.<sup>9</sup>

Solutions of the carbonium ions were obtained in the following way. A saturated solution of antimony pentafluoride in sulfur dioxide was prepared (at -10°). Portions (2 ml) of this solution were cooled to -78°, causing some antimony pentafluoride to crystallize from solution. To this suspension was added dropwise with stirring approximately 0.3 g of the appropriate halo ether. Slight warming was required to complete the ionization, whereupon a homogeneous solution resulted with only slight traces of color. Ion concentrations were approximately 10%. These operations were carried out in the laboratory atmosphere. This procedure

provides a simply way to generate carbonium ions in a highly reproducible manner.

Spectra were recorded either on a Varian Model A56-60A spectrometer with external TMS in deuteriochloroform as reference (0.5 ppm has been added to these chemical shifts to correct them to TMS in a capillary as reference) or on a Varian Model HA-60 spectrometer with TMS in a capillary as reference.

Methanolysis of the carbonium ions was accomplished by adding slowly the solution of the carbonium ion in sulfur dioxide to a suspension of methanol and potassium carbonate at -78°. Product isolation was accomplished by drowning the resulting suspension in water and extracting with pentane. Identification of products was made by glpc comparison of retention times with authentic samples and by nmr and infrared spectroscopy. None of the dihalo ethers retained halogen in the quenching experiments.

## Stable Carbonium Ions. XL.<sup>1a</sup> Protonated Aliphatic Thiols and Sulfides and Their Cleavage to Carbonium Ions

George A. Olah, Daniel H. O'Brien,<sup>1b</sup> and Charles U. Pittman, Jr.,<sup>1c</sup>

Contribution from the Department of Chemistry, Case Western Reserve University, Cleveland, Ohio 44106. Received January 21, 1967

**Abstract:** A series of protonated aliphatic thiols and sulfides have been studied in HSO<sub>3</sub>F-SbF<sub>5</sub>-SO<sub>2</sub> solution. S-protonation was observed at -60° by nmr spectroscopy with negligible exchange rates. At higher temperatures, protonated thiols cleave to carbonium ions. Protonated sulfides, except for tertiary alkyl ones, are resistant to cleavage up to +70°.

We have previously reported the nmr observation of protonated alcohols<sup>2,3</sup> and ethers.<sup>4</sup> We wish now to report the observation of S-protonated thiols and sulfides in the extremely strong acid, FSO<sub>3</sub>H-SbF<sub>5</sub>, at -60° and their cleavage to carbonium ions.

### Results and Discussion

**Protonated Thiols.** Aliphatic thiols are quantitatively protonated in FSO<sub>3</sub>H-SbF<sub>5</sub> diluted with SO<sub>2</sub> at -60°.

They show well-resolved nmr spectra with very slow exchange rates. Protonated hydrogen sulfide itself shows a sharp singlet at -6.60 ppm. Protonated methyl thiol (Figure 1) shows the methyl triplet at -2.95 ppm and a SH<sub>2</sub><sup>+</sup> quartet at -6.45 ppm ( $J_{H-H} = 8.0$  cps). Protonated ethyl thiol (Figure 2) shows

the methyl triplet at  $-1.48$  ppm, a methylene sextet at  $-3.37$  ppm, and a  $\text{SH}_2^+$  triplet having a complex central peak at  $-6.22$  ppm ( $J_{\text{H}-\text{H}} = 8.0$  cps). Assignments of derived chemical shifts and coupling constants of the protonated thiols studied: methyl, ethyl, *n*-propyl, isopropyl, *n*-butyl, isobutyl, *sec*-butyl, *t*-butyl, and *t*-amyl, are summarized in Table I.

**Figure 1.**

The protonated thiols are surprisingly stable to increase in temperature when compared to the corresponding protonated alcohols.<sup>3</sup> However, the mode of sample preparation is critical. If the sample is prepared by the addition of the diluted, cooled acid to the thiol, simple protonated species are not observed. The nmr spectra indicate that protonated thiols react readily with the excess thiol still present in the solution.

However, when prepared by the addition of thiol to acid, even protonated *t*-butyl thiol shows no appreciable decomposition at  $-60^\circ$ . The small peak at  $-4.0$  ppm in the spectrum of protonated *t*-butyl thiol (Figure

**Figure 2.**

3) can be attributed to trimethylcarbonium ion and is probably due to cleavage as a consequence of local heating during sample preparation. The intensity of this peak did not increase with time at  $-60^\circ$ . In contrast, all attempts to prepare protonated *t*-butyl alcohol results in complete formation of trimethylcarbonium ion even at  $-70^\circ$ .

Figure 3.

Figure 4.

Protonated *t*-butyl thiol slowly cleaves to trimethyl-

carbonium ion and protonated hydrogen sulfide when the temperature is increased to  $-30^\circ$  ( $t_{1/2} \approx 15$  min). Protonated *t*-amyl thiol (Figure 4) also cleaves at this temperature to dimethylethylcarbonium ion. The spectrum of this carbonium ion can clearly be seen in Figure 5.<sup>5</sup>

Protonated secondary thiols are stable at higher temperatures. Protonated isopropyl thiol cleaves slowly at  $0^\circ$  in  $\text{FSO}_3\text{H}-\text{SbF}_6$  (1:1) solution. No well-identified carbonium ion was found in the nmr spectra under these conditions, obviously due to the relative instability of the isopropyl cation at higher temperature giving a complex reaction mixture. Protonated *sec*-butyl thiol cleaves to trimethylcarbonium ion at this temperature.

(5) G. A. Olah, E. B. Baker, J. C. Evans, W. S. Tolgyesi, J. S. McIntyre, and I. J. Bastien, *J. Am. Chem. Soc.*, **86**, 1360 (1964).

Figure 5.

Figure 6.

Protonated primary thiols are stable at much higher temperatures. When prepared at  $0^\circ$  in  $\text{FSO}_3\text{H}-\text{SbF}_6$  (1:1), protonated *n*-butyl thiol shows slight decomposition to trimethylcarbonium ion attributable to local heating during sample preparation. The intensity of the trimethylcarbonium ion peak did not increase with time at this temperature. Protonated *n*-butyl thiol slowly cleaves to trimethylcarbonium ion only at  $+25^\circ$ .

**Protonated Sulfides.** Alkyl sulfides are quantitatively protonated in  $\text{FSO}_3\text{H}-\text{SbF}_6$  diluted with  $\text{SO}_2$  at  $-60^\circ$ .

They show well-resolved nmr spectra. Protonated dimethyl sulfide (Figure 6) shows the methyl doublet at  $-3.08$  ppm and the  $\text{SH}^+$  septuplet at  $-6.52$  ppm ( $J_{\text{H-H}} = 8.0$  cps). Protonated diethyl sulfide (Figure 7) shows the methyl triplet at  $-1.67$  ppm, a complex

$\text{CH}_3$ 1 $(\text{CH}_3\text{C}-)_2\text{SCH}_3$	-2.87 (2)	-1.67 (1)			-6.00 (4)	8.0
$\text{CH}_3$ 2b $\text{CH}_3$ 1 2a $\text{CH}_3\text{CSCH}<\begin{smallmatrix} \text{CH}_3 \\ \text{CH}_3 \end{smallmatrix}$	-4.05 (cm)	a -1.62 (2) b -1.73 (1)			-6.25 (2)	7.0

<sup>a</sup> From external capillary of TMS. <sup>b</sup> Multiplicity of peaks shown in brackets; (cm) = complex multiplet.

multiplet for the methylene hydrogens at  $-3.57$  ppm, and the  $\text{SH}^+$  quintet at  $-6.23$  ppm ( $J_{\text{H-H}} = 8.0$  cps). Assignments of derived shifts and coupling constants are summarized in Table II.

The proton on sulfur in the protonated thiols and sulfides is at considerably higher field ( $-6.52$  to  $-5.80$  ppm) than the corresponding proton on oxygen in protonated alcohols and ethers ( $-9.21$  to  $-7.88$  ppm).<sup>1,2,3</sup> It is worthy of note that protonated hydrogen sulfide appears as a sharp singlet with a similar chemical shift,  $-6.60$  ppm, indicating that the positive charge on protonated sulfur is delocalized and little influenced by alkyl substitution.

Protonated isopropyl sulfide (Figure 8) gave an unexpectedly complex pattern for the methyl hydrogens. It showed a pair of overlapping doublets separated by 3.5 cps at  $-60^\circ$ . It is highly unlikely that a preferred conformation can explain this multiplicity since the pair of doublets is still present at  $+70^\circ$  in a solution of  $\text{HSO}_3\text{F}-\text{SbF}_5$  (1:1). A more plausible explanation is the existence of intrinsic asymmetry in the  $-\text{HS}^+-\text{R}$  group comparable to that found in ethyl isopropyl sulfoxide, diethyl sulfoxide,<sup>6</sup> ethyl benzenesulfonate, diethyl acetal,<sup>7</sup> diethyl sulfite,<sup>8</sup> and ethyl perfluoro-

isopropanesulfinate.<sup>9</sup> This asymmetry results in non-equivalent methylene hydrogens in the ethyl groups of the first five listed compounds and nonequivalent

Figure 8.

Figure 9.

perfluoromethyl groups in the  $F^{19}$  spectrum of ethyl perfluoroisopropanesulfinate. The nmr spectrum of diisopropyl sulfoxide (Figure 9) displays a nonequivalent, overlapping methyl doublets separated by 2.5 cps when dissolved in  $SO_2$  at  $-60^\circ$ .

It is particularly noteworthy that nonequivalent methylene hydrogens were observed in the boron hydride addition complex of diethyl sulfide,  $(CH_3CH_2)_2S \cdot BH_3$ .<sup>6</sup> This would indicate that the bonding at sulfur in this compound and in the protonated sulfides is qualitatively similar. The existence of this asymmetry further confirms the fact that the exchange of the proton is extremely slow.

In other protonated sulfides where such multiplicity might be observed, protonated methyl isopropyl sulfide gave only one isopropyl methyl doublet; protonated *t*-butyl isopropyl sulfide gave only slight broadening of the isopropyl methyl doublet; and protonated diethyl sulfide gave a complex methylene peak because of the further splitting by the proton on sulfur.

The protonated sulfides are more stable to cleavage than the corresponding protonated ethers<sup>3</sup> and also more stable than the protonated thiols. Protonated methyl *t*-butyl ether is completely cleaved to trimethylcarbonium ion and protonated methanol upon sample preparation even at  $-70^\circ$ . Protonated methyl *t*-butyl

Figure 10.

Figure 11.

sulfide is stable at  $-60^\circ$  (Figure 10). The initial spectrum shows slight decomposition to trimethylcarbonium ion and protonated methyl thiol probably caused by local heating during sample preparation. No change in peak intensities with time was noted at  $-60^\circ$ . When the temperature is increased to  $-15^\circ$ , protonated methyl *t*-butyl sulfide very slowly cleaves to trimethylcarbonium ion and protonated methyl thiol.

Protonated di-*t*-butyl sulfide shows very little cleavage at  $-60^\circ$  (Figure 11). At  $-35^\circ$  it cleaves slowly ( $t_{1/2} \approx 1$  hr) to trimethylcarbonium ion and protonated hydrogen sulfide

Protonated secondary sulfides show extraordinary stability toward the strongly acidic medium. Protonated isopropyl sulfide shows no appreciable cleavage up to  $+70^\circ$  in a solution of  $\text{FSO}_3\text{H}-\text{SbF}_5$  (1:1). At this temperature it slowly decomposed. No nmr identifiable products were noted at this elevated temperature.

### Experimental Section

**Materials.** Thiols, symmetrical dialkyl sulfides, isopropyl methyl sulfide, and *t*-butyl methyl sulfide were reagent grade materials and were used without further purification.

*sec*-Butyl isopropyl sulfide was prepared according to the method of Vecera<sup>10</sup> by the reaction of *sec*-butylthiol in ethoxide-ethanol solution with isopropyl bromide. The product was purified by distillation. The fraction between  $139$  and  $140^\circ$  was used.

*t*-Butyl isopropyl sulfide was prepared according to the method of McAllan<sup>11</sup> by the reaction of *t*-butyl alcohol in 25% aqueous sulfuric acid with isopropylthiol. The product was purified by distillation. The fraction between  $130$  and  $132^\circ$  was used.

Isopropyl sulfoxide was prepared by the method of Addison<sup>12</sup> by the reaction of isopropyl sulfide with dinitrogen tetroxide.

(10) M. Vecera, J. Gasparic, D. Snobl, and M. Jurecek, *Chem. Listy*, **50**, 770 (1956); *Chem. Abstr.*, **50**, 15412a (1956).

(11) D. T. McAllan, T. V. Cullum, R. A. Dean, and F. A. Fidler, *J. Am. Chem. Soc.*, **75**, 3627 (1951).

(12) C. C. Addison and J. C. Sheldon, *J. Chem. Soc.*, 2705 (1956).

The product was purified by vacuum distillation. The fraction between  $91$  and  $92^\circ$  (12 mm) was used. The nmr spectra of the sulfoxide dissolved in sulfur dioxide at  $-60^\circ$  is shown in Figure 9.

**Nmr Spectra.** Varian Associates Model A-56-60A and HA 60-IL nmr spectrometers with variable temperature probes were used for all spectra. Samples of S-protonated thiols and sulfides were prepared by dissolving approximately 1.5 ml of  $\text{HSO}_3\text{F}-\text{SbF}_5$  (1:1 *M* solution) in an equal volume of sulfur dioxide and cooling to  $-76^\circ$ . The thiol or sulfide (approximately 0.2 ml) was dissolved in 1 ml of sulfur dioxide, cooled to  $-76^\circ$ , and with vigorous agitation slowly added to the acid solution. Samples prepared in this manner gave nmr spectra which showed no appreciable chemical shift differences with temperature or small concentration variations. The acid was always in excess of the sulfide or thiol as indicated by the large acid peak at  $-10.2$  ppm. Samples undiluted with sulfur dioxide were prepared by cooling the 1:1 *M* acid to  $0^\circ$  and adding, with vigorous agitation, the neat, cooled sulfide or thiol. The nmr spectra of such samples showed a downfield solvent shift of about 0.3 ppm for all peaks because of the absence of sulfur dioxide.

Protonated hydrogen sulfide was prepared by passing gaseous hydrogen sulfide for a short time through a stirred solution of 2 ml of 1:1  $\text{FSO}_3\text{H}-\text{SbF}_5$  diluted with 2 ml of sulfur dioxide and cooled to  $-76^\circ$ .

## Acid Anhydride-Free Acid Equilibria in Water in Some Substituted Succinic Acid Systems and Their Interaction with Aniline<sup>1</sup>

Takeru Higuchi,<sup>2</sup> Lennart Eberson, and John D. McRae

Contribution from the School of Pharmacy, University of Wisconsin, Madison, Wisconsin 53706. Received November 7, 1966

**Abstract:** The rates of formation of cyclic acid anhydrides in aqueous solutions of methyl-substituted succinic acids are shown to increase as expected with the degree of substitution. For the unsubstituted and mono- and di-substituted acids, at least, the estimated equilibrium concentration of the anhydride in the acid solution ranges from 1 to 50 ppm and appears to be largely determined by the rate of formation than by its hydrolysis. The aniline method was not found to be applicable to the tri- and tetrasubstituted acids because of the rapid formation of the corresponding imides.

Recent experimental evidence points to the existence of rather sluggish equilibria in water between certain sterically favored polycarboxylic acids and their corresponding cyclic internal anhydride.<sup>3</sup> Although such a process may be expected to be favored by, for example, alkyl substitution<sup>4</sup> in succinic acid, quantitative evaluation of such an effect had not been widely attempted, particularly on systems in which the relative concentration of the anhydride species would be expected to be low. The present report is concerned with results of an attempt to determine the rates of formation and the relative concentrations of these active species

in aqueous solutions of methyl-substituted succinates at several temperatures.

Direct spectrophotometric determination of the forward rate of reaction 1 as carried out recently<sup>5</sup> was

not possible in these systems since the relative concentrations of the anhydrides are always much too low to permit convenient determination. For the present purpose, the aniline method developed earlier for studies

Figure 1. Semilogarithmic plot of aniline concentration as a function of time in several methyl-substituted succinic acid buffers at pH 4.0 and 60°. All buffers were 0.06 *M*.

on the unsubstituted succinate system<sup>3</sup> was applied. The method is based on the observation that the formation of anilic acid in aqueous solutions of these dicarboxylic acids and aniline is mediated entirely through intermediate production of the corresponding cyclic anhydride, measurement of the rate of formation of the amide thus affording estimation of both the rate of formation of the anhydride and the equilibrium constant for the cyclization reaction.

## Results and Observations

**General Behavior of Aniline-Succinate Systems.** In Figure 1 the observed residual concentration of aniline in the presence of six methyl-substituted succinate buffers, 0.06 *M* at pH 4.0, is shown as a function of time at 60°. The initial concentration of the amine in each instance was 0.001 *M*. As is evident from the plots, the terminal phase of each reaction exhibited pseudo-first-order reaction kinetics. Since in the trimethyl and tetramethyl systems crystalline precipitates of the corresponding anils were observed, the over-all reaction appears to be

on the basis of previously established chemistry of the succinate system. The initial nonlinearity observed with the mono- and dimethyl systems is presumably due to buildup of the corresponding anilic acid.

If the above rationalization is correct, the indicated equilibrium between the dicarboxylic acid and the anilic acid occurs with increasing facility as the degree of substitution is increased. It is evident in the case of tri- and tetramethyl systems that the initial equilibria are established too quickly to permit convenient measurement of the unidirectional rate, at least at 60°.

Figure 2. Reciprocal plot of the initial rate of disappearance of aniline in pH 3.90 methylsuccinate buffer (0.6 *M*) at 60° as a function of the reciprocal initial aniline concentration.

Figure 3. Reciprocal plot of the initial rate of disappearance of aniline in pH 2.75, 2,2-dimethylsuccinate buffer (0.5 *M*), at 60° as a function of the reciprocal initial aniline concentration.

It appeared possible, however, in the remaining four systems to determine the initial rates of loss of aniline in the manner previously described for estimating the  $k_1$  values for these acids.

**Estimation of  $k_1$ .** The absolute rate of formation of the postulated acid anhydride species for monomethyl- and two dimethyl-substituted succinic acids was estimated by determining the limiting initial rate of reaction with excess aniline in these systems. The reciprocal of initial rates was plotted *vs.* the reciprocal of initial aniline concentrations to give plots such as those represented by Figures 2 and 3 for the methylsuccinate and 2,2-dimethylsuccinate buffer systems, respectively. The limiting initial rate represented by the intercept of such plots can be used to calculate  $k_1$ . The values of  $k_1$  obtained in this manner are shown in Figure 4 plotted in the usual Arrhenius manner against  $1/T$ , the actual range of temperature being 40–70° for the monomethylsuccinic system and 50–80° for two dimethylsuccinic systems. Measurement was not attempted in the case of the *meso*-dimethylsuccinate system because of the low solubility of the acid and because of

Figure 4. Arrhenius plots of  $k_1$ , the anhydride formation constant for four anhydrides.

its limited availability. Data for the unsubstituted succinic acid obtained earlier<sup>3</sup> are also included for comparison purposes. In Table I numerical values obtained at 60° are given, together with  $E_a$ , the energies of activation estimated from the Arrhenius plots. Eyring's  $\Delta H^\ddagger$  would differ from these by 0.66 kcal/mole. Entropies of activation have been calculated for  $k_1$  at 60° and are also included in Table I.

Table I. Rate of Cyclic Anhydride Formation in Water at 60°

Acid	$k_1 \times 10^7$ sec <sup>-1</sup>	$E_a$ , kcal/ mole	$-\Delta S^\ddagger$ , eu

Figure 5. Equilibrium constant for formation of cyclic anhydride in water plotted against  $1/T$ .

The values shown in the table for succinic acid require some explanation since the extrapolated constant at 25° of  $1 \times 10^{-6}$  differs significantly with that of  $0.2 \times 10^{-6}$  reported earlier.<sup>3</sup> In making the earlier estimate, the rate constants ( $k_1$ ) obtained experimentally at 95, 85, 75, and 65° for succinic acid were considered to form a curved rather than a linear Arrhenius plot, the nonlinear extrapolation yielding a rather rough estimate for  $K_{eq}$  of  $2 \times 10^{-7}$  at 25°. The slight departure from linearity is evident for the point shown in Figure 4. If, however, we assume that the line is more or less linear as are others of the series, the equilibrium constant at 25° for succinic comes out to be approximately  $1 \times 10^{-6}$ . The magnitude of the uncertainty introduced by extrapolation reflects the relatively high activation energy for the reaction. The higher equilibrium value for succinic anhydride would reduce the free energy of its hydrolysis from -9250 cal/mole recently calculated from our earlier data by Jencks, *et al.*,<sup>7</sup> to -8310 cal/mole.

The equilibrium constants given in Table II are shown plotted in Figure 5 against  $1/T$ . The enthalpic changes for cyclization of the four acids shown do not appear to differ significantly, the mean indicated heat of the reaction being of the order of 9 kcal/mole.<sup>8</sup> The plot for succinic acid appears to support the higher extrapolated value of the equilibrium value at 25° since it falls essentially on the line.

**Evaluation of  $k_2$ .** Determinations of  $k_2$ , the rate constant for reaction between free aniline and anhydride,

(7) W. P. Jencks, F. Barley, R. Barnett, and M. Gilchrist, *J. Am. Chem. Soc.*, **88**, 4464 (1966).

(8) The observed lack of dependence on methyl substitution is at variance with the conclusion drawn from calorimetric measurements (J. B. Conn, G. B. Kistiakowsky, R. M. Roberts, and E. A. Smith, *ibid.*, **64**, 1747 (1942)). These were, however, carried out on solid anhydrides and involved guesses as to heats of fusion. The mean value of 9 kcal is in reasonable agreement with the mean of the calorimetric estimates.

Figure 6. Plot of rates of hydrolysis of succinanic acids against rates of anhydride formation from corresponding acids.

were performed for five methyl-substituted succinic anhydrides. These determinations were made at 20, 25, and 30° at pH 4.65 using a 0.05 *M* buffer composed of an acid-salt system corresponding to the anhydride studied. The values of  $k_2$  obtained at 25°, based on free aniline concentration at the chosen pH, are shown in Table III. Check runs on methylsuccinic anhydride and aniline at pH 3.30 and 3.90 at 25° yielded results which agreed with that obtained at higher pH. The apparent heat of activation,  $E_a$ , for the formation of all the anilic acids was found to be essentially the same, about  $4.6 \pm 0.3$  kcal/mole.

Table III. Comparison of Rate of Reaction with Aniline,  $k_2$ , with Rate of Hydrolysis,  $k_{-1}$ , at 25°

Acid anhydride	$k_2, M^{-1} \text{ sec}^{-1}$	$k_1 \times 10^5, \text{ sec}^{-1}$
Succinic	19.3	2.64
Methylsuccinic	15.3	3.65
2,2-Dimethylsuccinic	5.3	2.84
<i>dl</i> -2,3-Dimethylsuccinic	9.2	3.95
<i>meso</i> -2,3-Dimethylsuccinic	13.4	5.73

## General Discussion

It is apparent from the data presented that substitution of methyl groupings for methylene hydrogens in succinic acid markedly increases the cyclization tendency as expected. The order and magnitude of the observed rate enhancement essentially parallel that recently reported for formation of the same anhydrides from the corresponding succinanic acids,<sup>9</sup> as is evident from the log-log plot of the specific rate constants as shown in Figure 6. Since the reverse hydrolytic reaction rates represented by  $k_{-1}$  in Table III are relatively unaffected by methyl substitution, the equilibrium points appear to be largely determined by the formation rate.

## Experimental Section

**Equipment and Reagents.** Mineral oil baths regulated to 0.05° were used for the kinetic runs to determine  $k_1$ . All final determinations of residual aniline were carried out spectrophotometrically

on a Cary Model 11 MS spectrophotometer. The adjustment and determinations of pH were made with a Beckman pH meter with an expanded scale.

Aniline was freshly distilled and kept under nitrogen. The methyl-substituted succinic acids used have been previously described.<sup>6</sup> The anhydrides were prepared by treating the corresponding acids with excess acetyl chloride and recrystallizing from anhydrous diethyl ether or diethyl ether-petroleum ether (bp 30-60°) mixtures. All other chemicals used were reagent or analytical grade.

**Procedure for Kinetic Runs to Determine  $k_1$ .** The several 0.5 or 0.06 *M* buffers at the desired pH also contained aniline in various concentrations. The ionic strength was adjusted to 1.0 with sodium chloride. These solutions were filled into glass ampoules of appropriate capacity, sealed under nitrogen, and then immersed in a thermostated mineral oil bath at the desired temperature. Ampoules were periodically withdrawn as samples and chilled to quench the reaction, after which a measured volume was withdrawn, made strongly alkaline with concentrated sodium hydroxide solution, and extracted with three portions of chloroform to remove residual aniline. The aniline concentration in the chloroform extract was determined spectrophotometrically at 287  $\mu$ . This procedure is essentially that reported earlier<sup>3</sup> except that sampling times were generally more frequent with the methyl-substituted succinic acids than with succinic acid since the former reacted more rapidly with aniline.

The dissociation constants employed in calculating  $k_1$  values were obtained potentiometrically in systems at 70° and in acid concentration conditions identical with those used in the rate studies. The values obtained are given as compound (molarity),  $pK_1$ ,  $pK_2$ ; succinic acid (0.5), 4.4, 4.8; methylsuccinic acid (0.6), 3.75, 5.15; 2,2-dimethylsuccinic acid (0.5), 3.80, 6.0; *dl*-2,3-dimethylsuccinic acid (0.5), 3.75, 5.65.

**Procedure for Determination of  $k_2$ .** These rate constants were determined in a conventional manner in a thermostated Cary Model 11 spectrophotometer. The reactions carried out directly in the photometer cell were made pseudo first order with respect to anhydride by using anhydride in 40-fold excess over the aniline concentration, with the latter having a zero-time concentration of about  $2.5 \times 10^{-4}$  *M*. The anhydride was first introduced into the reaction cell in varying amounts of dioxane such that the final dioxane concentration ranged from 3.2 to 19.2% on a volume basis. The aniline was next introduced in a 0.05 *M* buffer composed of the acid-salt system corresponding to the anhydride being studied in the reaction. The composition of the solution in the reference cell was identical except for the omission of anhydride. The increase in absorbance at 235  $\mu$  was used to follow the reaction rate. Semi-logarithmic plots of the equilibrium value of the absorbance minus the value of the absorbance at time  $t$ ,  $A_\infty - A_t$ , gave good first-order plots over several half-lives, and the resulting rate constants were then extrapolated to zero dioxane concentration. The second-order constants were calculated from these rate values on the basis of the anhydride concentration employed and the estimated value of  $f_2$ , the fraction of unprotonated aniline in the solution at the pH and temperature of the reaction.

The dissociation constant of aniline was determined spectrophotometrically at 20, 25, and 30° in the presence of buffers of the same concentration as used in the studies to determine  $k_2$ . The  $pK_a'$  of aniline determined in this manner was 4.81, 4.74, and 4.69, respectively, at 20, 25, and 30°.

In these studies, a buffer effect was noted on both  $k_2$  and, when determining the  $pK_a'$  of aniline, the fraction of total aniline present as the free amine. Increasing buffer concentration caused a decrease in both the value of  $k_2$  and in the fraction of free amine present, the magnitude of the effect being comparable in both cases. Since it is the free amine form that is postulated as the reactive species with the acid anhydrides, the decrease of the concentration of this form would be expected to reflect itself in a corresponding decrease in  $k_2$ . However, at concentrations of 0.05 *M* buffer, the values of  $k_2$  obtained differ by about only 2% or less from buffer-free values, and the values in Table III for  $k_2$  are uncorrected for buffer effects.

# The Products and Stereochemistry of Reactions of Dinitrogen Tetroxide with $\Delta^{9,10}$ -Octalin, Norbornene, Cyclooctatetraene, 6,6-Diphenylfulvene, and Indene

Harold Shechter, John J. Gardikes,<sup>1a</sup> Thomas S. Cantrell,<sup>1b,c</sup> and George V. D. Tiers<sup>1d</sup>

Contribution from the Department of Chemistry, The Ohio State University, Columbus, Ohio, and the Central Research Department, Minnesota Mining and Manufacturing Company, St. Paul, Minnesota. Received December 19, 1966

**Abstract:**  $\Delta^{9,10}$ -Octalin and dinitrogen tetroxide in ethyl ether in the presence of oxygen yield *trans*-9,10-dinitrodecalin (II) and 10-nitro-9-decalyl nitrate (III). Norbornene and dinitrogen tetroxide give, after hydrolysis and chromatography, *exo,cis*- (IX, major) and *trans*- (X, minor) 2,3-dinitrobicyclo[2.2.1]heptanes and 2-hydroxy-3-nitrobicyclo[2.2.1]heptane (stereochemistry unestablished). Cyclooctatetraene and dinitrogen tetroxide result in the formation of 5,8-dinitro-1,3,6-cyclooctatriene (XXII) of probable *trans* stereochemistry. The mechanisms of these reactions are consistent with homolytic addition of dinitrogen tetroxide or nitrogen dioxide to the olefinic centers to give vicinal nitrocycloalkyl radicals which then react selectively with the nitrating agent(s) from the more sterically accessible direction. Reaction of 6,6-diphenylfulvene and dinitrogen tetroxide leads to 4-benzhydrylidene-*cis*-3,5-dinitrocyclopentene (XXIX), 2-nitro-6,6-diphenylfulvene (XXX), and 2,5-dinitro-6,6-diphenylfulvene (XXXI). Indene and dinitrogen tetroxide and subsequent aqueous hydrolysis yield *cis*-2-nitro-1-indanol (XXXVI). The *cis* stereochemistry of the products derived from addition of dinitrogen tetroxide to 6,6-diphenylfulvene and to indene may indicate that with rigid planar cycloolefins (charge transfer) coordination with dinitrogen tetroxide, and subsequent collapse to *cis* adducts, becomes an important reaction mechanism.

Dinitrogen tetroxide reacts with olefins (eq 1) in ether or ester-type solvents and in the presence of oxygen to give vicinal dinitro compounds, nitro nitrites, nitro nitrates.<sup>2</sup> These reactions involve coordina-

tion of dinitrogen tetroxide with the electron-donor olefins and subsequent homolytic addition of the nitrating agent(s) to the olefins.<sup>2</sup> Dinitrogen tetroxide reacts stereoselectively to a number of olefins and cycloolefins. Cyclohexene and cyclopentene give both *cis* and *trans* products.<sup>3</sup> 1-Methylcyclohexene yields 1-methyl-*trans*-2-nitrocyclohexyl nitrite exclusively.<sup>3</sup> *cis*- and *trans*-stilbenes and dinitrogen tetroxide give mixtures of the *dl*- and *meso*-dinitro adducts in a 3:2 ratio and the *threo* and *erythro* nitro nitrites in a 2:1 ratio.<sup>4</sup> It has been suggested that the major stereoisomeric adducts are formed more rapidly because the structure of the transition state for homolytic reaction of an intermediate nitroalkyl radical ( $\text{R}_2\text{C}-\text{CR}_2\text{NO}_2$ ) with the nitrating agent ( $\text{NO}_2$ ,  $\text{N}_2\text{O}_4$ ) resembles the reagents and thus attack occurs at the greater rate from the more accessible direction.<sup>2,4a,5</sup>

In the present study the stereochemistry of addition of dinitrogen tetroxide to  $\Delta^{9,10}$ -octalin, bicyclo[2.2.1]heptene-2, cyclooctatetraene, 6,6-diphenylfulvene, and indene has been investigated. The principal objectives of this research are to evaluate possible charge-transfer and steric effects in reactions of dinitrogen tetroxide with the particular olefins. The chemistry of the products of these reactions has also been determined.

## Discussion

**$\Delta^{9,10}$ -Octalin.** Addition of  $\Delta^{9,10}$ -octalin (I) in ethyl ether to dinitrogen tetroxide in ethyl ether at  $-20^\circ$  in the presence of oxygen (eq 2) yields *trans*-9,10-dinitrodecalin (II, 76% conversion of I) as the principal product; small amounts of 10-nitro-9-decalyl nitrate (III, eq 2; stereochemistry unknown) were isolated (see Experimental Section) in certain experiments. Upon inverting the order of addition of reactants at  $0^\circ$  in the

absence of oxygen, *trans*-9,10-dinitrodecalin (II, 74%) is also obtained. The order of addition of reagents does not significantly affect the types and stereochemistry of the products formed. When oxygen is passed rapidly through the reaction mixture, there is a significant change in the course of addition and 10-nitro-9-decalyl nitrate (III) is a major product.

The stereochemistry of *trans*-9,10-dinitrodecalin (II) was assigned upon its hydrogenation (eq 3) over Raney

(5) Reaction of *trans*-stilbene with dinitrogen tetroxide to give *dl*-1,2-dinitro-1,2-diphenylethane and *threo*-1-(2-nitro-1,2-diphenylethyl) nitrite as the principal products may be formally classified as that in which *cis* addition is preferred.<sup>4a</sup>

(a) The studies of reactions of dinitrogen tetroxide with  $\Delta^{9,10}$ -octalin and norbornene have been abstracted in part from the Ph.D. dissertation of J. J. Gardikes, The Ohio State University, Columbus, Ohio, 1960. This research was supported by the Office of Naval Research. (b) The investigations of dinitrogen tetroxide with cyclooctatetraene, 6,6-diphenylfulvene, and indene were effected by T. S. Cantrell, Ph.D. Dissertation, The Ohio State University, Columbus, Ohio, 1964. (c) National Science Foundation Cooperative Fellow, 1962 and 1963–1964, and National Science Foundation Graduate Fellow, 1962–1963. (d) The nuclear magnetic resonance spectra of *cis*- and *exo,trans*-2,3-dinitrobicyclo[2.2.1]heptanes and *exo,cis*- and *trans*-2,3-diacetamidobicyclo[2.2.1]heptanes were studied by G. V. D. Tiers of the Minnesota Mining and Manufacturing Co., St. Paul, Minn. (e) H. Shechter, *Record Chem. Progr.*, **25**, 55 (1964). (f) J. C. D. Brand and I. D. R. Stevens, *J. Chem. Soc.*, 629 (1958). (g) H. Shechter and J. J. Gardikes, *J. Am. Chem. Soc.*, **81**, 5420 (1959); (h) T. Stevens, *ibid.*, **81**, 3593 (1959).

nickel to *trans*-9,10-diaminodecalin (IV, 97% yield) and subsequent conversion to *trans*-9,10-diacetamidodecalin and *trans*-9,10-diaminodecalin dipicrate. The assignment of structure of *trans*-9,10-diaminodecalin (IV) was made after synthesis of *cis*-9,10-diaminodecalin (VI) and *cis*-9,10-diacetamidodecalin by reaction of *cis*-decalin-9,10-dicarboxylic anhydride (V) with hydrazoic acid<sup>6</sup> and sulfuric acid (eq 4) and subsequent acetylation of the product. The stereochemical assign-

ments of structure of II, IV, and VI are in agreement with previous intuitive assignments for these products as obtained from (1) nitration of *cis*- and *trans*-decalins<sup>7</sup> and *trans*-9-nitrodecalin<sup>7c</sup> (eq 5) and (2) reduction of 1,6-cyclodecanedione dioxime with sodium and ethyl alcohol<sup>8</sup> (eq 6).

The formation of *trans*-9,10-dinitrodecalin (II) from  $\Delta^{9,10}$ -octalin indicates that dinitrogen tetroxide adds to the unsaturated center by a *trans* process. The stereochemical results thus exclude a concerted or bimolecular reaction involving coordinative *cis* attack of dinitrogen tetroxide on the carbon-carbon double bond. Synthesis of *trans*- (II) rather than *cis*-9,10-dinitrodecalin may be interpreted in terms of a homolytic addition process involving initial formation of the 10-nitro-9-decalyl radical (VII) and subsequent exchange with dinitrogen tetroxide or electron pairing with nitrogen dioxide. On the basis that radical pairing or exchange processes involve small activation energies and are usually exothermic, it is anticipated that the structure of the transition state for reaction of the 10-

nitro-9-decalyl radical (VII) with the nitrating agent is close to reactants and will reflect the trigonal ( $sp^3$ ) character of the tertiary radical which results in partial flattening of each of the fused cyclohexane rings from their chair forms. In the reaction of the 10-nitro-9-decalyl radical (VII) to give the *trans* adduct (II, eq 7), a maximum of four partial 1,3 interactions with the

nitrating agent will be involved, whereas for formation of the *cis*-dinitro adduct, there will be three more prohibitive 1,2 interactions, one of which is with a bulky nitro group.<sup>9</sup> It is also of note that the generation and fate of VII in the present system are identical with that proposed for liquid-phase nitration of *trans*-9-nitrodecalin to II.<sup>7c</sup>

10-Nitro-9-decalyl nitrate (III) can be made a minor or major reaction product by the amount of oxygen introduced during addition. Its structure was assigned from its quantitative and infrared analyses and upon consideration of its probable origin. 10-Nitro-9-decalyl nitrate (III) may possibly arise (eq 8) from addition of oxygen to the 10-nitro-9-decalyl radical (VII), reaction of the 10-nitro-9-decalylperoxy radical with dinitrogen tetroxide or nitrogen dioxide, homolytic decomposition of 10-nitro-9-decalyl pernitrate, and exchange or electron pairing of the resulting 10-nitro-9-decalyloxy radicals with the nitrating agent(s).<sup>1</sup> An additional or alternate source of III may be reaction of VII with nitrogen trioxide ( $\cdot NO_3$ ).<sup>2</sup>

**Norbornene.** Reaction of norbornene (VIII) with dinitrogen tetroxide in ethyl ether at 0°, rapid aqueous hydrolysis of the initial adducts, and chromatography of the products on silica gel (eq 9) results in formation of *exo,cis*-2,3-dinitrobicyclo[2.2.1]heptane (IX, 22% conversion of VIII; mp 108°); *trans*-2,3-dinitrobicyclo[2.2.1]heptane (X, 12%; mp 127°), and 2-hydroxy-3-nitrobicyclo[2.2.1]heptane (XI, 33%; stereochemistry unestablished). There is net isomerization of IX to X on chromatography; however, under conditions of near-kinetic control involving rapid chromatography and minimal handling of the products, the principal

(6) Schmidt reactions of hydrazoic acid with carboxylic acids give amines with retention of configuration: H. Wolff, *Org. Reactions*, **3**, 307 (1946).

(8) P. A. Plattner and J. Halstkamp, *Helv. Chim. Acta*, **27**, 200 (1944).

(9) (a) The relative thermodynamic stabilities of *cis*- and *trans*-9,10-dinitrodecalins are not known. *trans*-Decalin is 2.1 kcal more stable than is *cis*-decalin;<sup>10</sup> however, *cis*-9-methyldecalin derivatives are slightly more stable than are *trans*-9-methyldecalin derivatives.<sup>10</sup> *cis*-9-Decalylcarboxylic acid is also thermodynamically more stable than the *trans* isomer.<sup>11</sup> (b) G. F. Davies and E. C. Gilbert, *J. Am. Chem. Soc.*, **63**, 1585 (1941); (c) A. Ross, P. A. S. Smith, and A. S. Dreiding, *J. Org. Chem.*, **20**, 905 (1955); (d) R. E. Pincock, E. Grigat, and P. D. Bartlett, *J. Am. Chem. Soc.*, **81**, 6332 (1959).

dinitro adduct was of *exo,cis* (IX) rather than of *trans* (X) stereochemistry. *endo,cis*-2,3-Dinitrobicyclo[2.2.1]heptane (XII) was not found.

The gross structures of IX and X were indicated from their analyses and infrared properties; that the adducts are related stereochemically was established by isomerization of X to IX<sup>10</sup> (eq 10a) on chromatography or by the action of catalytic quantities of piperidine, cyclohexylamine, sodium methoxide, and potassium *t*-butoxide. The fact that addition of dinitrogen tetroxide

to VIII occurs without carbon-skeleton rearrangement<sup>11</sup> is demonstrated by oxidation of IX and X with alkaline potassium permanganate to *cis*-1,3-cyclopentanedicarboxylic acid in excellent yields. Behavior of IX as a vicinal dinitro compound which will undergo base-catalyzed elimination of nitrous acid (eq 10b) is indicated by its reaction with equivalent amounts of sodium ethoxide to give 2-ethoxy-3-nitrobicyclo[2.2.1]heptane (XV, stereochemistry unknown).

The stereochemistries of IX and X are assigned on the basis of their chromatography properties and their dipole moments. The nuclear magnetic resonance of IX and X and of their derivatives in which there has been no stereochemical alteration about the functional

(10) This appears to be the first recorded example of base-catalyzed isomerization of a vicinal dinitro compound. Such dinitro compounds are usually converted to conjugated nitroolefins by bases. In the present system isomerization of the vicinal dinitro compound may be allowed because collapse of XIII to XIV is a relatively slow process because of the strain involved.

(11) Possibly anticipated if addition of dinitrogen tetroxide occurred by an electrophilic process.

centers corroborate the structural assignments.<sup>12</sup> The evidence for the structures of IX and X is as follows.

It has been previously observed that rigid cyclic compounds having dinitro groups in *cis* positions are much more strongly adsorbed<sup>13</sup> than are their corresponding *trans* isomers. The enhanced adsorptive properties of such *cis* derivatives have been attributed to their greater dipole moments and to the relatively favorable steric circumstances for interaction of the polar nitro groups with the adsorbent.<sup>13</sup> Chromatography of the vicinal dinitro products of the present research revealed quickly that the adduct melting at 108° is more strongly adsorbed on silica gel than is the isomer of 127° melting point. The assignments initially made are that the isomers melting at 108 and 127° are the *exo,cis* (IX) and the *trans* (X) adducts, respectively. The stereochemical designations are compatible with the dipole moments subsequently determined for IX (6.1 D.) and X (3.4 D.).<sup>14</sup>

The structures of IX and X also agree with their nuclear magnetic resonance properties. The spectrum of the isomer melting at 108° (IX) shows, *inter alia*, a doublet of area 2 at  $\tau$  5.09 ( $J \sim 2$  cps) attributable only to the hydrogens on the carbon atoms C-2 and C-3 containing the nitro groups. The observed equivalence of these hydrogens indicates that IX is either the *exo,cis* or *endo,cis* isomer. The corresponding hydrogens in the isomer melting at 127° (X) exhibit significantly different chemical shifts, appearing at  $\tau$  4.52 (pair of doublets,  $J \sim 4$  cps) and  $\tau$  4.93 (pair of doublets,  $J \sim 3.9$  cps,  $J \sim 1.4$  cps);<sup>15</sup> X, therefore, possesses the *trans* stereochemistry.

The hydrogen signals at C-7 provide evidence for the assignment of the *cis* nitro groups of IX as *exo* rather than *endo*. The apical hydrogens (C-7) of X occur as a complex multiplet overlapping the signals of the C-5 and C-6 methylenes at  $\tau$  8–8.5. In the spectrum of IX, on the other hand, one apical hydrogen is half of a broadened AB quartet at  $\tau$  7.45; the other half is partially masked by the C-5 and C-6 methylenes at  $\tau$  8.4 but appears to occur at *ca.*  $\tau$  8.56. The low-field position of one hydrogen at C-7 in IX is consistent with its location as *syn* to the two *exo* nitro groups. Models reveal that the nitro groups of IX are probably parallel to each other and perpendicular to the C-2–C-3 bond; the *syn* C-7 hydrogen is thus in the deshielding region. An effect of the magnitude found in IX would not be expected from proximity to only one nitro group (as in the *trans* isomer) or for the *endo,cis*-dinitro adduct.

*trans*-2,3-Diacetamido[2.2.1]heptane, mp 272–274°, has been previously prepared.<sup>16</sup> A chemical proof of

(12) Efforts to resolve either of the 2,3-dinitrobicyclo[2.2.1]heptanes by reaction of insufficient brucine,  $\alpha$ -phenethylamine, and potassium menthylate were unsuccessful.

(13) D. B. Miller, Ph.D. Dissertation, The Ohio State University, 1957.

(14) The theoretical moments of IX and X as calculated using simple trigonometric methods involving vector addition of group moments are 6.3 and 2.2 D., respectively. It is not yet clear why the observed value for X is somewhat greater than that calculated. The enhanced dipole moment obtained for X does not affect the stereochemical assignments given to IX and X.

(15) The coupling constants are consistent with those previously observed in norbornane systems; see P. Laszlo and P. von R. Schleyer, *J. Am. Chem. Soc.*, **86**, 1171 (1964); E. I. Snyder and B. Franzus, *ibid.*, **86**, 1166 (1964).

the stereochemistry of compounds IX and X was initiated. Hydrogenation of IX and X over platinum in glacial acetic acid<sup>17</sup> gives the corresponding diamines as isolated in near-quantitative yields as dibasic acetates (XVI and XVIII, eq 11 and 12). Reactions of XVI and XVIII with acetic anhydride (eq 11 and 12) yield

the corresponding diacetylated derivatives, *exo,cis*-2,3-diacetamidobicyclo[2.2.1]heptane (XVII, mp 272° uncor; 83% yield) and *trans*-2,3-diacetamidobicyclo[2.2.1]heptane (XIX, mp 280° uncor; 84% yield). A mixture of XVII and XIX results in melting point depression.

Since there are only small differences in melting points for the diacetamido derivatives prepared previously<sup>18</sup> and presently, it is not possible to make structural assignments on such evidence.<sup>18</sup> The nuclear magnetic resonance for XVII and XIX are decisive, however, and corroborate the stereochemical assignments given IX and X. In the spectrum of XVII (in trifluoroacetic acid) the equivalent hydrogens at C-2 and C-3 appear as a broadened doublet at  $\tau$  5.64; in the spectrum of XIX the hydrogens at C-2 and C-3 are nonequivalent and occur as separate unresolved multiplets at  $\tau$  5.81 and 6.23. Thus XIX is assigned the *trans* structure and XVIII the *cis* for reasons analogous to that discussed for the nuclear magnetic resonance of IX and X.

Isolation of IX as the major dinitro adduct from dinitrogen tetroxide and VIII indicates that the principal stereochemical path involves *exo-cis* addition. *exo-cis* processes involving free-radical mechanisms have been observed in reactions of *p*-thiocresol,<sup>19a</sup> ethyl bromoacetate,<sup>19b</sup> and bromotrichloromethane,<sup>19c</sup> respectively, with VIII, and in homolytic reaction of hydrogen bromide and 2-bromo-2-norbornene.<sup>19d</sup> The major stereochemical path in the present system thus may be

(17) The acidic solvent is necessary to prevent isomerization during the reductions.

(18) Authentic XIX was no longer available from ref 16c and its synthesis is laborious.

(19) (a) S. J. Cristol and G. D. Brindel, *J. Am. Chem. Soc.*, **76**, 5699 (1954); (b) J. Weinstock, Abstracts, 128th National Meeting of the American Chemical Society, Minneapolis, Minn., 1955, p 190; (c) V. A. Rollen, *Dissertation Abstr.*, **19**, 960 (1958); (d) N. A. LeBel, *J. Am. Chem. Soc.*, **82**, 623 (1960).

interpreted in terms of a homolytic process involving sterically preferred *exo* attack on VIII by the nitrating agent to give the *exo*-3-nitro-2-norbornyl radical (XX, eq 13), and subsequent exchange with dinitrogen tetroxide or electron pairing with nitrogen dioxide from the more accessible directions (eq 13). An alternate possibility is that a portion of the *exo,cis* product (IX) is formed *via* coordination of the olefinic center of VIII with dinitrogen tetroxide from the lesser hindered direction (*exo*) and subsequent *cis* addition. Systems in which this latter mechanism appears to be important have been found and will be discussed in this paper.

The 2-hydroxy-3-nitrobicyclo[2.2.1]heptane (XI) obtained from VIII and dinitrogen tetroxide is presumably derived from hydrolysis of 2-(3-nitrobicyclo[2.2.1]heptyl) nitrites. The structure of XI is confirmed by its analysis and infrared absorption (see Experimental Section), its oxidation by basic potassium permanganate to *cis*-1,3-cyclopentanedicarboxylic acid, and its conversion by acetic anhydride to 2-acetoxy-3-nitrobicyclo[2.2.1]heptane<sup>20</sup> in 70% yield. The stereochemistry and isomeric composition of XI were not determined. It is probable that XI is a mixture of *exo,cis*-2-hydroxy-3-nitro and *endo*-2-hydroxy-*exo*-3-nitro isomers.

**Cyclooctatetraene.** Dinitrogen tetroxide and cyclooctatetraene (XXI) in ethyl ether at  $-70^\circ$  give 5,8-dinitro-1,3,6-cyclooctatriene (XXII, eq 14) in >34% yield; other products formed decompose rapidly at room temperature and cannot be handled readily.<sup>21</sup>

Use of inverse addition techniques or excess XXI does not improve the yield of XXII or result in other tractable products. XXII decomposes rapidly and often violently in 1–2 hr; its ability to be handled is generally improved when it is purified.

From its analysis and spectral properties the product of reaction of XXI and dinitrogen tetroxide must be a 1:1 dinitro adduct. Its probable structure includes XXII, 1,2-dinitro-3,5,7-cyclooctatriene (XXIII), 1,8-dinitro-1,3,5,7-octatetraene (XXIV), derivatives of bi-

(20) (a) Ethanolic solutions of 2-acetoxy-3-nitrobicyclo[2.2.1]heptane and of IX in excess base give ultraviolet absorption with maxima at 245 m $\mu$ ; the extinction coefficients (max) are 11,310 and 11,428, respectively. Since salts of primary and secondary nitro compounds usually absorb at 229–235 m $\mu$  with  $\lambda_{\text{max}} \sim 11,000$ , it is believed that the bathochromic shifts in absorption of the present bicyclic nitronates result from the diminished  $\pi$ -bond order of the C–N bonds in these strained ground states in excitation processes involving further diminution of the  $\pi$  order. (b) F. T. Williams, P. W. K. Flanagan, W. J. Taylor, and H. Shechter, *J. Org. Chem.*, **30**, 2674 (1965).

(21) Adducts such as 1,2-dinitro-3,5,7-cyclooctatriene (XXIII) and 1-nitro-2-nitro-3,5,7-cyclooctatriene are expected to isomerize to unstable products such as 1,8-dinitro-1,3,5,7-octatetraene (XXIV) and 1-nitro-8-nitro-1,3,5,7-octatetraene. Multiple addition of dinitrogen tetroxide to these rearrangement products and to XXI also probably occurs.

[4.2.0]octadiene (XXV and XXVI), and those containing phenyl or cycloheptatriene groups.<sup>22</sup> The

violet spectrum of the present adduct exhibits no maximum but only a shoulder at 240–245 m $\mu$  strong end absorption; its infrared spectrum indicates strong bands for nitro groups (6.46 and 7.48  $\mu$ ) saturated carbon but none for aromatic nuclei or conjugated nitroolefins. The spectral properties of the compound strongly suggest that it is a 1,3,6-cyclooctatriene.<sup>23</sup> Its ultraviolet spectrum is very similar to that of 5,8-bis(2-cyano-2-propyl)-1,3,6-cyclooctatriene, the product of 1,4-homolytic addition of 2-cyano-2-propyl radicals and XXI.<sup>24</sup>

The nuclear magnetic resonance of the adduct clearly indicates benzenoid, cycloheptatriene, and bicyclo[4.2.0]octadiene structures. The absence of aryl hydrogen signals at  $\tau$  2.5–3.0 eliminates any benzene derivative; the lack of resonance in the  $\tau$  5.0–6.5 region indicates the absence of tertiary hydrogen on carbon atoms which do not bear nitro groups, thus ruling out bicyclooctadiene or cycloheptatriene structures. The complex absorption in the  $\tau$  7.7 region is consistent with the structure assigned to XXII.

Direct experimental evidence is available on the stereochemistry of XXII; its instability precludes determination of its dipole moment. *cis*-Bimolecular addition of dinitrogen tetroxide on XXI appears unlikely because of steric features of the cyclooctatetraene ring. The stereochemistry of XXII is probably *trans* because 4-nitro-2,5,7-cyclooctatriene-1-yl radical (XXVII), a presumed intermediate, will strongly reflect a conformation in which the nitro group is quasi-equatorial rather than quasi-axial, and subsequent reaction with the nitrating agent can proceed most readily in the quasi-equatorial direction.<sup>25</sup>

**4-Diphenylfulvene.** Addition of dinitrogen tetroxide to 6,6-diphenylfulvene (XXVIII) in ethyl ether in the absence of oxygen and subsequent hydrolysis of the initial products (eq 16) give 4-benzhydrylidene-

For a summary of the types of structures derivable by addition to cyclooctatetraene, see R. A. Raphael in "Nonbenzenoid Aromatic Compounds," D. Ginsburg, Ed., Interscience Publishers, Inc., New York, N. Y., 1959, Chapter 10.

1,3,5-Cyclooctatriene, bicyclo[4.2.0]octadiene, and cycloheptachromophores possess strong absorption maxima in the 265–275 m $\mu$  region; see M. Kamlet and H. Ungnade, Ed., "Organic Electronic Spectral Data," Vol. I and II, Interscience Publishers, New York, N. Y., 1963.

J. L. Kice and T. S. Cantrell, *J. Am. Chem. Soc.*, **85**, 2298 (1963). When the nitro group is quasi-equatorial in XXVII or if the stereochemistry (one of the nitro groups must take an axial position), models reveal that severe steric interference will exist between the quasi-equatorial nitro group and the carbon atoms of the ring.

*cis*-3,5-dinitrocyclopentene (XXIX, 22–28%), 2-nitro-6,6-diphenylfulvene (XXX, 2–4%), and 2,5-dinitro-6,6-diphenylfulvene (XXXI, 9–12%). Inverse addition of the reagents in the absence of oxygen at 0° yields the same product but in different proportions: XXIX (14–16%), XXX (1–2%), and XXXI (15–16%). There is considerable oxidation and polymerization of XXVIII by dinitrogen tetroxide. Direct addition using 10–15% excess XXVIII leads to the highest yields of

tractable products: XXIX (45–52%), XXX (3–4%), and no XXXI.

The elemental analysis, molecular weight, and absorption spectra of 4-benzhydrylidene-*cis*-3,5-dinitrocyclopentene (XXIX), a white solid, are consistent with its structure. The infrared absorption bands of XXIX at 6.42 and 7.31  $\mu$  are characteristic of saturated secondary nitro groups. Its ultraviolet spectrum exhibits a shallow maximum at 250 m $\mu$  ( $\epsilon$  10,200)<sup>26a</sup> and is similar to that of 1,1-diphenylethylene [ $\lambda_{\max}$  251 m $\mu$  ( $\epsilon$  12,000)]; its absorption is quite different from that of 3-benzhydrylidene-3,5-dinitrocyclopentene [ $\lambda_{\max}$  290 m $\mu$  ( $\epsilon$  19,000)].<sup>26b</sup> It is thus apparent that XXIX possesses the 1,1-diphenylethylene chromophore and is the product of 1,4 addition of dinitrogen tetroxide across the five-membered ring of XXVIII. The stereochemistry of XXIX is assigned on the basis of its dipole moment. The calculated moments for the *cis* and *trans* isomers of 4-benzhydrylidene-3,5-dinitrocyclopentene are 5.60 and 0.98 D., respectively. The moment determined experimentally is 5.71 D., nearly identical with that anticipated for XXIX. Products obtained under relatively mild conditions were searched for 4-benzhydrylidene-*trans*-3,5-dinitrocyclopentene, but none was found. Some may have been formed initially and subsequently transformed to XXX and XXXI. Even if such an unlikely circumstance leads exclusively to the XXX and XXXI isolated, these products are formed in such minor amounts that it can be concluded that addition of dinitrogen tetroxide to XXVIII occurs primarily by a *cis* reaction path.

(26) (a) E. A. Braude and W. F. Forbes, *J. Chem. Soc.*, 2014 (1950); (b) J. L. Kice and F. M. Parham, *J. Am. Chem. Soc.*, **80**, 3792 (1958).

2-Nitro-6,6-diphenylfulvene (XXX) is a brick red solid. Its infrared spectrum shows bands for a conjugated nitro group at 6.61 and 7.40  $\mu$ . Its ultraviolet spectrum exhibits maxima at 374, 290, and 254  $m\mu$  ( $\epsilon$  23,500, 11,100, and 12,000) and is similar in shape to that of XXVII with a bathochromic shift of *ca.* 50  $m\mu$ . Further evidence for the structure of XXX is that it is obtained in 63% yield by treating XXIX with triethyl-

amine in benzene (eq 17). When triethylamine is added to a reaction mixture of XXVIII and dinitrogen tetroxide (without hydrolysis), XXX is isolated in 55% yield.

2,5-Dinitro-6,6-diphenylfulvene (XXXI), an orange solid, has infrared absorption for conjugated nitro groups at 6.69 and 7.53  $\mu$ . Its ultraviolet absorption maxima at 399 and 308  $m\mu$  ( $\epsilon$  29,000 and 12,700) are shifted bathochromically as anticipated upon comparison with that of XXX. The structure of XXXI is established chemically upon effecting its synthesis from XXIX by chlorination in warm chloroform (eq 18).

The result of particular interest in the present system is that the major (or sole) initial product of reaction of XXVIII and dinitrogen tetroxide is derived from *cis* rather than *trans* 1,4 addition. The stereochemistry is unexpected on the basis of stepwise homolytic addition of nitrogen dioxide and subsequent stereochemical control since attack of the nitrating agent from the lesser hindered side of the intermediate nitrocycloalkenyl radical XXXII will yield the *trans* adduct XXIII (eq 19).

It is possible that the *cis*-dinitro compound XXIX is formed *via* a process in which the dinitrogen tetroxide first forms a charge-transfer or addition complex with the diene system of XXVIII (eq 20). Dinitrogen

tetroxide does give 1:1 adducts with benzene, mesityl-

ene, and nitrobenzene which are believed to be derived from orbital overlap<sup>27</sup> of the  $\pi$ -electron systems of the compounds with dinitrogen tetroxide. Coordination of dinitrogen tetroxide and XXVIII as indicated (eq 20) may indeed occur since the cyclopentadienylidene moiety is a rigid and electron-rich planar  $\pi$  system. Formation and collapse *via* XXXIV and XXXV may thus possibly be favored because the process allows maximum overlap and minimal steric restriction of the reactants.

**Indene.** Addition of dinitrogen tetroxide in ethyl ether to indene (XXXVI) in ethyl ether at 0° and subsequent hydrolysis of the initial products gives *cis*-2-nitro-1-indanol (XXXVII, eq 21) as the only well-defined product. Major reactions result in amorphous

products and black resins<sup>28a</sup> containing nitro groups. Inverse addition enhances formation of intractables<sup>28b</sup> and decreases the nitroindanol XXXVII. Attempts to convert the primary products advantageously to 2-nitroindene (XXXIX) by treatment of the reaction mixture with triethylamine were unsuccessful.

The gross structure of 2-nitro-1-indanol (XXXVII) is derived from its analytical and spectral properties (infrared bands at 6.50 and 2.98  $\mu$  for nitro and hydroxyl groups) and its conversion (eq 21) to *cis*-1-acetoxy-2-nitroindane (XXXVIII) and to 2-nitroindene (XXXIX), a previously established structure,<sup>29</sup> by reaction with acetic anhydride and subsequent elimination by sodium acetate.

The stereochemistry of XXXVIII, and consequently of XXXVII, is assigned on the basis of the nuclear magnetic resonance properties of the hydrogen atoms at C-3. The nuclear magnetic resonance of a number of 1,2-disubstituted indanes of known stereochemistry has been recently determined.<sup>30</sup> For the *trans* compounds containing either electronegative or electropositive substituents, the signals due to the hydrogens at C-3 occur as quartets with differences of chemical shifts of 23–44 cps; the methylene hydrogens, however, of the corresponding *cis* isomers absorb as doublets at very nearly the same field, the difference in chemical shifts being only 0–3 cps for the compounds studied. In the spectrum of XXXVIII, the methylene hydrogens absorb as doublets centered at  $\tau$  6.37 ( $J = 7.4$  cps) and 6.40 ( $J = 7.0$  cps) with a difference of 2 cps. On the basis of the generalization reported,<sup>30</sup> the stereochemistries of XXXVII and XXXVIII are assigned as *cis*.

That the sole tractable product of reaction of indene (XXVI) and dinitrogen tetroxide is derived from *cis* addition is not in agreement with a stepwise homolytic

(27) C. C. Addison and J. C. Sheldon, *J. Chem. Soc.*, 1941 (1956).

(28) (a) Indene is polymerized by free-radical or electrophilic reagents.<sup>28b</sup> (b) "Encyclopedia of Organic Chemistry," Vol. 12A, Elsevier Publishing Co., Inc., New York, N. Y., 1948, p 101.

(29) O. Wallach and E. Beschke, *Ann.*, 336, 2 (1904).

(30) W. E. Rosen, L. Dorfman, and M. Linfield, *J. Org. Chem.*, 29, 1723 (1964).

process; attack of the nitrating agent from the preferred direction by such a mechanism would give the *trans* adduct. As has been suggested for reaction of XXVIII and dinitrogen tetroxide, the *cis* stereochemistry of XXXVII may result from initial coordination of dinitrogen tetroxide with XXXVI, a nearly flat rigid cycloolefin having considerable  $\pi$  electron activity, and subsequent intramolecular collapse with minimum reorganization. It is of note that the *cis* stereochemistry of reaction of dinitrogen tetroxide and indene (XXXVI) is analogous to that observed for addition of performic acid<sup>20</sup> and of deuterium bromide<sup>21</sup> to XXXVI. It has been suggested that the latter reaction occurs by a classical carbonium ion process involving ion pairs. It is conceivable that reaction of dinitrogen tetroxide with XXXVII (and with XXVIII) involves collapse of an initial  $\pi$  adduct *via* an intimate ion pair process or *via* transition states having considerable cationic rather than homolytic character.

*cis*-1-Acetoxy-2-nitroindane (XXXVIII) is also of interest in that it is converted by potassium carbonate to 1-(2-nitro-1-indenyl)-2-nitroindane (XXXII, eq 22), the product of self-Michael addition of 2-nitroindene

(XXXIX). Analytical, molecular weight, and spectral data allow the structural assignment of XXXXII. The infrared spectrum of XXXXII has strong bands at 6.47 and 6.66  $\mu$  indicating the presence of both conjugated and unconjugated nitro groups. Maximum ultraviolet absorption of XXXXII occurs at the same wavelength as does 2-nitroindene (XXXIX; 338  $m\mu$ ) but of only one-half the intensity. The adduct is assigned structure XXXXII rather than as the isomer XXXXIII on the basis that the nmr spectrum showed only one methylene signal of intensity 2.

## Experimental Section

**Reaction of  $\Delta^9,10$ -Octalin (I) with Dinitrogen Tetroxide. Inverse Addition.**  $\Delta^9,10$ -Octalin mixture<sup>22</sup> (68 g, 0.277 mole of I,  $n_D^{20}$  1.4938)

(31) M. J. S. Dewar and R. C. Fahey, *J. Am. Chem. Soc.*, **85**, 2248 (1963).

(32) (a) The I used was a mixture of  $\Delta^9,10$ -octalin (I, 55.4%),  $\Delta^1,9$ -octalin (28%), and decalin (16.6%) prepared by reduction of naphthalene with lithium in ethylamine.<sup>22b</sup> The presence of  $\Delta^1,9$ -octalin complicated separation and identification of the products of reaction with dinitrogen tetroxide but did not affect the principal stereochemical objectives of

in ethyl ether (250 ml) was added dropwise to dinitrogen tetroxide (138 g, 1.5 moles) in ethyl ether (750 ml) at  $-20^\circ$ . Oxygen was passed through the reaction mixture only while the octalin was added. The mixture was then kept between  $-10$  and  $20^\circ$  for 45 hr. A bluish crystalline solid was filtered which, after having been washed with a small quantity of cold ethyl ether and air dried, was identified as *trans*-9,10-dinitrodecalin (II, 33.4 g), mp  $150$ – $159^\circ$ . After the reaction solution had been poured on ice, washed with water, 10% aqueous sodium bicarbonate, and water, dried over magnesium sulfate, and concentrated, additional II (16.0 g) was obtained, mp  $149$ – $159^\circ$ . The total II isolated was 49.4 g (0.217 mole). Recrystallization of II from hot ethanol gave 47.7 g of pure material (76% conversion of I to II, mp  $168^\circ$  cor, lit.<sup>7</sup>  $164^\circ$ ).

Complete evaporation of the ethereal filtrate left a yellow oil (50.6 g) from which no solid could be crystallized. Distillation of an aliquot of the material allowed separation of decalin,<sup>23</sup>  $n_D^{20}$  1.4695, equivalent to 11.3 g (0.083 mole) in the evaporated filtrate. The remaining material exhibited absorption for olefin, nitro (6.47  $\mu$ ), and nitrate (6.13  $\mu$ ) groups; its various components could not be adequately resolved (see subsequent Experimental Section) because of their drastic decomposition upon chromatography on silica gel or on vacuum distillation.

In a similar experiment in which oxygen was bubbled through the mixture for the entire reaction period, a solid of different composition was obtained. From this solid, after several recrystallizations from alcohol, was isolated II, mp  $161$ – $164^\circ$ , and an analytically pure product, 9-nitro-10-nitrodecalin (III), mp  $122$ – $124^\circ$ , of unknown stereochemistry (probably *trans*). The infrared spectrum of III exhibits absorptions for a nitro group at 6.45  $\mu$  and for nitrate at 6.13 and 7.8  $\mu$ .

Anal. Calcd for  $C_{10}H_{14}N_2O_4$ : C, 49.17; H, 6.60; N, 11.45. Found: C, 49.31; H, 6.41; N, 11.45.

**Direct Addition.** Dinitrogen tetroxide (13.8 g, 0.15 mole) in ethyl ether (75 ml) was added in 1 hr at  $0^\circ$  to  $\Delta^9,10$ -octalin reagent<sup>22b</sup> (13.6 g, 0.055 mole of I) in ethyl ether. After 8 hr, II precipitated (6.1 g), mp  $155$ – $160^\circ$ , and was filtered. The filtrate was handled as described previously to give additional II (3.7 g), decalin, and nitro derivatives.<sup>24</sup>

**Reduction of *trans*-9,10-Dinitrodecalin (II).** *trans*-9,10-Diaminodecalin (IV), *trans*-9,10-Diacetamidodecalin, and *trans*-9,10-Diaminodecalin Dipicrate. *trans*-9,10-Dinitrodecalin (II, 2.0 g, 0.0088 mole) in 15% absolute ethanol in benzene (50 ml) was hydrogenated over Raney nickel (45 psi) at room temperature for 6 hr. Filtration of the catalyst and evaporation of the solvents gave crude *trans*-9,10-diaminodecalin (IV, 1.435 g, 0.0085 mole), mp  $65$ – $67^\circ$ , 96.6% conversion of II. Pure IV was obtained as white needles upon one recrystallization from cold ethyl ether, mp  $70^\circ$ , lit.<sup>7</sup>  $70^\circ$ . *trans*-9,10-Diacetamidodecalin (white crystals) prepared from reaction of IV with acetic anhydride and 10% sodium hydroxide melted above  $360^\circ$ ; the *trans*-9,10-diaminodecalin dipicrate prepared melted at  $262$ – $264^\circ$ , lit.<sup>8</sup>  $262$ – $264^\circ$ .

**Synthesis of *cis*-9,10-Diaminodecalin (VI) and *cis*-9,10-Diacetamidodecalin.** Sodium azide (1.95 g, 0.03 mole) in concentrated sulfuric acid (25 ml) was added dropwise to a stirred mixture of decalin-9,10-dicarboxylic anhydride (2.08 g, 0.01 mole, mp  $89$ – $91^\circ$ , lit.<sup>25</sup> mp  $95$ – $96^\circ$ ) and fuming sulfuric acid at  $56$ – $60^\circ$ . After 7 hr, evolution of gas had ceased, and the reaction mixture was cooled and poured on ice. The solution was made basic and then extracted several times with ethyl ether. The ether extract was dried over magnesium sulfate and evaporated to give crystalline *cis*-9,10-diaminodecalin (VI, 0.4 g, 0.0024 mole), mp  $41^\circ$ , lit.<sup>8</sup>  $41^\circ$ , 24.0%

this study. (b) R. A. Benkeser, R. E. Robinson, D. M. Sauve, and O. H. Thomas, *J. Am. Chem. Soc.*, **77**, 3230 (1955); W. G. Dauben, E. C. Martin, and G. J. Fonken, *J. Org. Chem.*, **23**, 1205 (1958); A. S. Hussey, J. F. Sauvage, and R. H. Baker, *ibid.*, **26**, 256 (1961); see R. A. Benkeser and E. M. Kaiser, *ibid.*, **29**, 955 (1964).

(33) Its infrared spectrum and refractive index are essentially identical with that of authentic decalin.

(34) A considerable portion of the noncrystalline product, as separated by chromatography on silica gel, is soluble in excess sodium hydroxide. The ultraviolet absorption of an alkaline solution of this material in ethanol shows a minimum at 234  $m\mu$  and a maximum at 283  $m\mu$  ( $\lambda_{max}$  9700) analogous to that of conjugated nitroanates.<sup>26b</sup> The ultraviolet absorption and the nuclear magnetic resonance of this material indicate the presence of a carbon-carbon double bond and a  $CHNO_2$  function. It is probable that a constituent of the reaction product is 1-nitro- $\Delta^9,10$ -octalin. For further experiments on the products, see ref 1a.

(35) K. Alder and K. H. Backendorf, *Ber.*, **71**, 2199 (1938).

conversion of decalin-9,10-dicarboxylic anhydride. Reaction of VI with acetic anhydride and 10% sodium hydroxide yielded *cis*-9,10-diacetamidodecalin, mp 243°, lit.<sup>9</sup> 242°.

**Reaction of Norbornene (VIII) with Dinitrogen Tetroxide.** Dinitrogen tetroxide (4.6 g, 0.6 mole) in ethyl ether (200 ml) was added in 2 hr at 0–5° to norbornene (VIII, 37.6 g, 0.4 mole) in ethyl ether (500 ml). After 4 hr the mixture was poured into water (500 ml), stirred for 0.5 hr, and washed quickly with 5% aqueous sodium bicarbonate (400 ml),<sup>10</sup> dilute hydrochloric acid, and water. After the ether solution was evaporated, the oily residue was stirred several hours with water (three 400-ml portions). The water-insoluble oil was redissolved in ether, dried over magnesium sulfate, evaporated to about 200 ml, and cooled with ice. The white solid which separated was filtered, washed with a small quantity of cold ether, air dried, and then identified as *exo,cis*-2,3-dinitrobicyclo[2.2.1]heptane (IX, 7.7 g), mp 108°, infrared absorption for an aliphatic nitro group at 6.45  $\mu$ .

*Anal.* Calcd for  $C_7H_{10}N_2O_4$ : C, 45.16; H, 5.41; N, 15.04. Found: C, 45.47; H, 5.46; N, 15.09.

The remaining ethereal filtrate was evaporated and the yellow residue (28.8 g) chromatographed on silica gel (G. F. Smith Co., 3.5  $\times$  21 cm) prewashed with 1:1 Skellysolve B–methylene chloride (200 ml). The following eluents were used: 1:1 Skellysolve B–methylene chloride (1200 ml), methylene chloride (1000 ml), and 4:1 methylene chloride–ethyl acetate (500 ml). Seven equal fractions (about 400 ml) were collected. Fractions 1 (16.7 g) and 2 (2.3 g) show identical spectra for a mixture of IX and X. Fractions 3 (0.5 g), 4 (1.0 g), 5 (2.4 g), 6 (1.7 g), and 7 (3.5 g), though different, show bands for hydroxyl, nitro, and carbonyl (5.8  $\mu$ ) groups; their principal component is 2-hydroxy-3-nitrobicyclo[2.2.1]heptane (XI).

Fraction 1 (1.0-g aliquot) was rechromatographed on silica gel ( $P_{200}$  = 160 ml) prewashed with Skellysolve B (200 ml).<sup>11</sup> The following solvents were used: Skellysolve B (150 ml), 4:1 Skellysolve B–methylene chloride (150 ml), 3:2 Skellysolve B–methylene chloride (150 ml), 3:2 methylene chloride–Skellysolve B (150 ml), and methylene chloride (100 ml). Ten fractions (1'–10') of approximately 70 ml each were collected. Fractions 1' and 2' contained only a small amount of product (0.03 g); this material exhibited bands for nitro (6.48  $\mu$ ) and possibly nitrate (6.12  $\mu$ ) groups. Fractions 3'–5' yielded a white solid, *trans*-2,3-dinitrobicyclo[2.2.1]heptane (X, 0.46 g), mp 127–130°.

*Anal.* Calcd for  $C_7H_{10}N_2O_4$ : C, 45.16; H, 5.41; N, 15.04. Found: C, 45.03; H, 5.43; N, 15.21.

The total amount of X in fractions 1 and 2 is 8.73 g, 0.047 mole, 11.8% conversion of VIII. Fractions 6'–10' yielded *exo,cis*-2,3-dinitrobicyclo[2.2.1]heptane (IX, 0.46 g), mp 108–110°; the amount of IX calculated in fractions 1 and 2 is 8.7 g. The total amount of IX isolated from the reaction is 16.4 g, 0.008 mole, 22% conversion of VIII.

From the aqueous washes of the initial reaction product after addition of sodium chloride, extraction with ether, drying of the ether extracts over magnesium sulfate, and vacuum evaporation of the ether, was isolated crude 2-hydroxy-3-nitrobicyclo[2.2.1]heptane (XI, 20.6 g, 0.131 mole, 33% conversion of VIII).<sup>12</sup> Distillation of VIII at greatly reduced pressures resulted in its extensive decomposition. The proof of structure of XI is described in subsequent experiments.

**Oxidation of IX, X, and XI to Cyclopentane-*cis*-1,3-dicarboxylic Acid with Potassium Permanganate.** To a solution of potassium permanganate (3.16 g, 0.02 mole) in water (50 ml) was added *exo,cis*-2,3-dinitrobicyclo[2.2.1]heptane (IX, 1.86 g, 0.01 mole). The mixture was warmed on a steam bath for 2 hr and then kept at 25–30° for 4 hr. The manganese dioxide was filtered, the solu-

tion was acidified, further traces of manganese dioxide were filtered, and finally the solution was extracted several times with ether. The ether solution was dried over magnesium sulfate and evaporated; the white solid (mp 118°) obtained was washed with a small quantity of cold Skellysolve F–ether, air dried, and then identified as cyclopentane-*cis*-1,3-dicarboxylic acid (1.01 g, 0.0064 mole), mp 120°, no depression by an authentic sample, 64% conversion of IX.

By procedures essentially identical with that described, X and XI were each oxidized by potassium permanganate to cyclopentane-*cis*-1,3-dicarboxylic acid, mp 118°, no depression by an authentic sample.

**2-Acetoxy-3-nitrobicyclo[2.2.1]heptane.** Concentrated sulfuric acid (five drops) was added to XI (8.4 g, 0.53 mole) in acetic anhydride (25 ml). The reaction mixture became hot and was heated (about 50°) further for 1.5 hr, and then stored at 25–30° for 24 hr. The resulting black solution was poured into water (100 ml), and the mixture stirred for 0.5 hr. After the mixture had been extracted with ether, the combined ether extracts were washed with 5% aqueous sodium bicarbonate, water, dilute aqueous hydrochloric acid, and water, dried over magnesium sulfate, and evaporated. The yellow oil obtained was distilled at reduced pressure to give 2-acetoxy-3-nitrobicyclo[2.2.1]heptane (7.4 g, 0.37 mole), bp 92–93° (0.3 mm),  $n_D^{20}$  1.4807, 70% conversion.

*Anal.* Calcd for  $C_9H_{12}NO_4$ : C, 54.24; H, 6.58; N, 7.04. Found: C, 54.01; H, 6.51; N, 7.19.

**Isomerization of *exo,cis*-2,3-Dinitrobicyclo[2.2.1]heptane (IX) with Piperidine.** *exo,cis*-2,3-Dinitrobicyclo[2.2.1]heptane (IX, 1.86 g, 0.01 mole) in ethyl ether (160 ml) was treated with piperidine (0.21 g, 0.0025 mole) in ether (20 ml). A solid formed immediately upon addition of piperidine. After 5 min the mixture was filtered; the ether solution was washed with water, excess aqueous hydrochloric acid, and water, and dried over magnesium sulfate and the solvent evaporated. The white solid isolated upon recrystallization from Skellysolve B was *trans*-2,3-dinitrobicyclo[2.2.1]heptane (X, 1.20 g, 0.00645 mole), mp 127°, 64.5% conversion of IX.

**Attempted Isomerization of *exo,cis*-2,3-Dinitrobicyclo[2.2.1]heptane (IX) with Pyridine.** *exo,cis*-2,3-Dinitrobicyclo[2.2.1]heptane (IX, 0.93 g, 0.005 mole, in ethyl ether (80 ml) was treated with pyridine (0.2 g, 0.0025 mole). There was no precipitation. After 5 min the ether solution was washed with water, excess aqueous hydrochloric acid, and water, dried over magnesium sulfate, and evaporated. All of the starting material was recovered, mp 108°; its infrared absorption spectrum was identical with that of authentic IX.

**Attempted Thermal Isomerization of *exo,cis*-2,3-Dinitrobicyclo[2.2.1]heptane (IX).** *exo,cis*-2,3-Dinitrobicyclo[2.2.1]heptane (IX, 0.5 g), mp 108°, was heated slowly to 160° (20 min) and then allowed to cool to room temperature. Upon heating IX slowly turned red and sublimed. Both the sublimed and recovered solids gave the same melting point, 106°; their infrared spectra were identical with the starting material.

**Reaction of *exo,cis*-2,3-Dinitrobicyclo[2.2.1]heptane (IX) with Sodium Ethoxide.** Sodium methoxide (1.62 g, 0.03 mole) was added portionwise to *exo,cis*-2,3-dinitrobicyclo[2.2.1]heptane (IX, 5.58 g, 0.03 mole) in absolute ethanol (50 ml) and stored for 0.5 hr. The resulting yellow mixture was poured in water (200 ml) and extracted with ether. After the extract had been washed with water, dilute acid, and water, dried over magnesium sulfate, and evaporated, the remaining oil was distilled. A colorless fraction (1.5 g, 27% yield) which analyzed for 2-ethoxy-3-nitronorbornane was obtained, bp 63–64° (0.3 mm),  $n_D^{20}$  1.4748, infrared absorption bands for nitro (6.49  $\mu$ ) and possibly ether (9.16  $\mu$ ) groups; there was no absorption for a carbon–carbon double bond.

*Anal.* Calcd for  $C_9H_{12}NO_3$ : C, 58.35; H, 8.16; N, 7.56. Found: C, 58.37; H, 8.35; N, 7.77.

**Reduction of *exo,cis*-2,3-Dinitrobicyclo[2.2.1]heptane (IX).** *exo,cis*-2,3-Dinitrobicyclo[2.2.1]heptane (IX, 1.86 g, 0.01 mole) in glacial acetic acid (50 ml) was hydrogenated over platinum (45 psi) at room temperature for 24 hr. After the catalyst had been filtered, the mixture was frozen, and the solvent sublimed under reduced pressure. A white ether-insoluble, water-soluble solid was obtained which begins melting at 110°. After having been washed with ether and air dried, the total solid weighed 2.36 g, 96% conversion of IX; based on the diacetate salt of *exo,cis*-2,3-diaminobicyclo[2.2.1]heptane (XVI). Treatment of the salt with picric acid in ethanol gave the dipicrate of *exo,cis*-2,3-diaminobicyclo[2.2.1]heptane, mp 245°.

*Anal.* Calcd for  $C_{15}H_{20}O_{14}N_2$ : C, 39.05; H, 3.45; N, 19.17. Found: C, 39.59; H, 3.43; N, 18.50.

(36) Prolonged treatment (24 hr) of IX and X in ethyl ether with 5% aqueous sodium bicarbonate gave oils which exhibit absorption for hydroxyl and nitro groups.

(37) When large amounts of IX (4.7 g) are chromatographed on silica gel (3.5  $\times$  20 cm) with Skellysolve B, there is some isomerization to X; this isomerization is not observed when a small amount (1.0 g) of IX is chromatographed on a similar column. Solutions of IX and X in ethyl ether and in methylene chloride upon standing for long periods turn yellow. The infrared spectra of the yellow solids isolated upon evaporation of the solvents, however, show no change of IX and X. There is depression in melting point upon mixing IX with X.

(38) The XI in fractions 3–7 is not included in the per cent conversion reported; the value thus quoted is believed to be minimal. In other experiments in which the initial reaction mixture was extracted thoroughly with water, the conversion of VIII to XI is considerably greater than 40%.

**Normal Addition, Excess XXVIII.** Dinitrogen tetroxide (12.4 g, 0.135 mole) in ethyl ether (35 ml) was added in 1 hr under nitrogen to a stirred solution of XXVIII (34.5 g, 0.150 mole) in ethyl ether (700 ml) at 0°. The mixture was stirred at 0° for 1.5 hr and then filtered. The crude XXIX (3.41 g) was washed twice with cold ether and air dried. The combined ethereal washings and filtrate were washed with water, dried, and concentrated to ca. 400 ml. Cooling to 5° gave additional crude XXIX (7.47 g). The mother liquor was concentrated to ca. 125 ml and cooled again. There was obtained a total of 11.87 g of an orange solid which was mainly XXIX contaminated with a little XXX. Further concentration and cooling of the mother liquors gave only red tar. The final crop of orange solid obtained above was ground and triturated with 4:1 hexane-benzene. The yellow residue, crude XXIX (11.03 g, total crude XXIX: 21.91 g, 0.0682 mole, 50% yield), was combined with the two crops obtained earlier and the whole recrystallized from chloroform-ethyl acetate (charcoal) to give pure XXIX, mp 165° dec. The total yield of pure XXIX was 20.0 g (0.062 mole, 46% based on dinitrogen tetroxide).

The benzene-hexane washings from the trituration of the third crop of XXIX were evaporated to give XXX (0.66 g, 0.0024 mole, 1.4% based on dinitrogen tetroxide). The reaction of dinitrogen tetroxide with excess XXVIII in ethyl ether at 0° thus gave XXIX (46% yield) and XXX (1.4% yield). Two additional experiments repeated as indicated gave analogous results: XXIX (45 and 52%) and XXX (1 and 3.5%).

**Reaction of 4-Benzhydrylidene-*cis*-3,5-dinitrocyclopentene (XXIX) with Triethylamine.** A solution of 4-benzhydrylidene-*cis*-3,5-dinitrocyclopentene (XXIX, 0.50 g, 0.00155 mole) and triethylamine (0.20 g, 0.0020 mole) in benzene (15 ml) was refluxed under nitrogen for 15 min. The dark red solution was evaporated to dryness under reduced pressure. The residue was taken up in a small amount of benzene and chromatographed on neutral alumina (20 × 200 mm, activity II). The column was eluted with hexane (100 ml) and 6:1 hexane-benzene (300 ml). A broad red band which moved down the column with the benzene-hexane was collected and evaporated to dryness. The residue was dissolved in warm 10% benzene-hexane (3 ml). On cooling the solution at -15°, 2-nitro-6,6-diphenylfulvene (XXX) crystallized as tiny dark red prisms, mp 111-113° dec; a total of 0.27 g (0.00098 mole, 63% yield) was obtained.

**Conversion of 4-Benzhydrylidene-*cis*-3,5-dinitrocyclopentene (XXIX) to 2,5-Dinitro-6,6-diphenylfulvene (XXXI).** 4-Benzhydrylidene-*cis*-3,5-dinitrocyclopentene (XXIX, 0.62 g, 0.00193 mole) was dissolved in boiling chloroform (25 ml) and a stream of chlorine was passed through the refluxing solution for 2 hr. The solvent was then evaporated and the red semicrystalline residue was chromatographed on silica gel (20 × 220 mm). Elution with 2:1 hexane-methylene chloride gave an orange solid identified as 2,5-dinitro-6,6-diphenylfulvene (XXXI, 0.19 g, 0.00058 mole, 31%) by its infrared spectrum.

**Reaction of 6,6-Diphenylfulvene (XXVIII) and Dinitrogen Tetroxide and Subsequent Treatment with Triethylamine.** A solution of 6,6-diphenylfulvene (XXVIII, 4.60 g, 0.020 mole) in ethyl ether (150 ml) was flushed with nitrogen, and dinitrogen tetroxide (1.70 g, 0.0185 mole) in ethyl ether (10 ml) was added at 0° under nitrogen. The addition required 40 min, after which the mixture was stirred for 20 min; triethylamine (2.2 g, 0.022 mole) was then added, and the mixture was stirred at 0° for 0.5 hr and at room temperature for 2 hr.

After the mixture had been evaporated to ca. 10 ml, it was chromatographed on neutral alumina (30 × 300 mm, activity II). Elution with 20% ether-hexane (400 ml) developed a deep red zone, leaving a dark brown zone at the top of the column. The red zone was eluted with 20% ether-hexane and the solvent evaporated. The residue was recrystallized from 20% benzene-hexane at -15°

to give 2-nitro-6,6-diphenylfulvene (XXX, 2.91 g, 1.04 moles, 52%), mp 111° dec.

**Reaction of Dinitrogen Tetroxide with Indene (XXXVI).** Dinitrogen tetroxide (18.4 g, 0.02 mole) in ethyl ether (40 ml) was added in 1 hr to a stirred solution of indene (XXXVI, 24.0 g, 0.21 mole) in ethyl ether (200 ml) at 0° in the absence of oxygen. The solution was stirred for 1.5 hr and filtered. The polymeric white solid formed (0.81 g) was washed with cold ether and air dried. The substance melted with decomposition over a broad range, exhibited the behavior of polymers, and was not further studied.

The filtrate was washed with water, dried, and concentrated to ca. 50 ml. Cooling to 5° and trituration with hexane resulted in partial crystallization. The solid, after having been washed with cold 1:2 ether-hexane, weighed 6.5 g. The mother liquor was combined with the wash liquid, reconcentrated, and cooled to -15°. A second crop of 2-nitro-1-indanol (XXXVII, mp 115-117°) was obtained which weighed 1.7 g; total yield, 8.2 g (0.046 mole, 23%). Two recrystallizations from ethyl acetate gave pure XXXVII as white silky needles, mp 117-118°.

*Anal.* Calcd for  $C_{11}H_{11}NO_2$ : C, 60.51; H, 5.02; N, 7.84. Found: C, 60.88; H, 5.15; N, 7.82.

Chromatography of the mother liquor on silica gel and elution with various solvents gave only brown gums. Use of the inverse addition technique gave increased amounts of the polymer and greatly decreased yields of nitro alcohol.

**Acetylation of 2-Nitro-1-indanol (XXXVII).** Sulfuric acid (three drops) was added to 2-nitro-1-indanol (XXXVII, 4.00 g, 0.022 mole) in acetic anhydride (75 ml). The solution was stored at room temperature overnight and then poured into ice water (300 ml). The suspension was stirred for 1 hr and extracted with ether. The combined ethereal extracts were washed with 5% sodium bicarbonate and water, dried, and evaporated to dryness. The residue crystallized on scratching and was recrystallized twice from ethanol (charcoal) to give 1-acetoxy-2-nitroindane (XXXVIII, 4.34 g, 0.0194 mole, 87%) as large colorless prisms, mp 62-63°.

*Anal.* Calcd for  $C_{11}H_{11}NO_4$ : C, 59.75; H, 4.98. Found: C, 60.22; H, 4.91.

**Conversion of 1-Acetoxy-2-nitroindane (XXXVIII) to 2-Nitroindene (XXXIX).** A solution of 1-acetoxy-2-nitroindane (XXXVIII, 2.00 g, 0.009 mole) in ethyl ether (40 ml) was refluxed over sodium acetate (0.3 g) for 35 hr. The solution was filtered, washed twice with water, dried, and evaporated to give a yellow solid residue. Recrystallization from benzene gave 2-nitroindene (XXXIX, 1.04 g, 0.0066 mole, 73%) as stout yellow needles, mp 139-140°. The ultraviolet spectrum of XXXIX showed  $\lambda_{max}^{CHCl_3}$  336 and 241 m $\mu$  ( $\epsilon$  26,000 and 35,000). The nmr spectrum showed, in addition to the aromatic hydrogen signals at  $\tau$  2.4-2.8, a triplet of area 1 at  $\tau$  2.11 (vinyl hydrogen), and a doublet of area 2 at  $\tau$  6.08 (methylene hydrogens);  $J = \sim 1.4$  cps.

**Preparation of 1-(2-Nitro-1-indenyl)-2-nitroindane (XXXXIII) from 1-Acetoxy-2-nitroindane (XXXVIII).** A solution of 1-acetoxy-2-nitroindane (XXXVIII, 0.90 g, 4.1 mmoles) in ethyl ether (20 ml) was refluxed over potassium carbonate (0.70 g, 7.8 mmoles) for 3 hr. The dark brown solution was filtered while still warm. The residue was extracted twice with ether, and the extracts were combined with the filtrate. The combined ether solution was treated with charcoal, filtered, and evaporated to give a brown oil which partially solidified on trituration with 1:1 benzene-hexane. Recrystallization of the solid from 1:1 benzene-hexane gave 1-(2-nitro-1-indenyl)-2-nitroindane (XXXXIII, 0.16 g, 0.51 mmole, 22%) as tiny, dull yellow prisms, mp 193-194° dec. The compound exhibited strong infrared bands at 6.47 and 6.66  $\mu$ ; the ultraviolet spectrum shows  $\lambda_{max}$  338 m $\mu$  ( $\epsilon$  11,000).

*Anal.* Calcd for  $C_{15}H_{14}N_2O_4$ : C, 67.92; H, 4.41. Found: C, 68.16; H, 4.31.

# Solvolysis of 6-Bicyclo[3.1.1]heptyl Tosylates<sup>1</sup>

Kenneth B. Wiberg and B. Andes Hess, Jr.<sup>2</sup>

Contribution from the Department of Chemistry, Yale University, New Haven, Connecticut. Received February 2, 1967

**Abstract:** The acetolysis and ethanolysis of *exo*- and *endo*-6-bicyclo[3.1.1]heptyl tosylates have been studied. The tosyl group must occupy the pseudo equatorial position on a cyclobutane ring in order to permit a high degree of participation. The *endo:exo* ratio was about 10%. Using the rate of borohydride reduction of the corresponding ketone as a model, both epimers appeared to react at an accelerated rate. The products of the reactions have been determined; the *endo* isomer gives mainly the 2-norcaranyl acetates, whereas the *exo* isomer gives a variety of products. The ratio of the products is not significantly solvent dependent.

We have previously shown that *endo*-5-bicyclo[2.1.1]hexyl tosylate undergoes acetolysis at a rate 10<sup>6</sup> faster than the *exo* isomer.<sup>3</sup> The remarkably high *endo:exo* ratio has prompted us to investigate two series of isomeric cyclopropylcarbiny, cyclobutyl, and allylcarbiny derivatives.<sup>4</sup> We now wish to report on the part of this investigation which deals with the bicyclo[3.1.1]heptanes. The syntheses of the compounds to be discussed are reported elsewhere.<sup>5</sup>

The rates of solvolysis of *endo*-6-bicyclo[3.1.1]heptyl tosylate (I) and of the *exo* isomer II were determined in glacial acetic acid and in two ethanol-water mixtures. In all cases, the reactions proceeded to completion; no internal return was noted. The data are summarized in Table I.

Table I. Rates of Solvolysis of 6-Bicyclo[3.1.1]heptyl Tosylates

Tosylate	Solvent	Temp, °C	<i>k</i> , sec <sup>-1</sup>	Δ <i>H</i> ‡, kcal/mole	Δ <i>S</i> ‡, eu
<i>endo</i>	HOAc	17.0	1.70 × 10 <sup>-3</sup>	20.1	+2
		32.0	9.90 × 10 <sup>-3</sup>		
		25.0	4.44 × 10 <sup>-3</sup>		
	80% EtOH	25.0	2.40 × 10 <sup>-3</sup>		
	95% EtOH	25.0	4.61 × 10 <sup>-3</sup>		
<i>exo</i>	HOAc	97.7% EtOH	2.92 × 10 <sup>-3</sup>	28.5	+4
		115.0	8.84 × 10 <sup>-3</sup>		
		130.0	3.61 × 10 <sup>-4</sup>		
		120.0	1.43 × 10 <sup>-4</sup>		
	80% EtOH	25.0	1.01 × 10 <sup>-3</sup>		
		120.0	2.47 × 10 <sup>-4</sup>		
	97.7% EtOH	120.0	2.73 × 10 <sup>-4</sup>		

\* Extrapolated values.

The products of the solvolyses were determined by isolation of the product mixtures followed by vpc separation and identification of individual components by comparison of the nmr and infrared spectra with those of authentic samples. The result, in the case of the *endo* isomer, was fairly simple (see Scheme I). In the ethanolysis experiment, the alcohols were identified by treatment of the reaction mixture with acetyl chloride followed by separation of the acetates. The

Scheme I

ethers were not separated and identified as such, but the vpc curve for the ether mixture was quite similar to that for the acetate mixture (except at shorter retention times) suggesting that the ethers were formed in about the same ratio. The ether:alcohol ratio was 88:12.

The solvolyses of the *exo* isomer led to more complex product mixtures. The data are summarized in Table II. Since the reaction conditions for acetolysis (5 hr, 130°) might lead to further reactions of the products initially formed, the stability of the products was investigated. A mixture of *cis*- and *trans*-2-norcaranyl acetates was found to isomerize to 4-cycloheptenyl acetate. *exo*-Bicyclo[3.1.0]hexane-6-methyl acetate (VII) was found to be partially converted to *trans*-2-vinylcyclopentyl acetate under the reaction conditions.

In the solvolysis in 80% ethanol, the ratio of ethers to alcohols was 30:70. In the absence of base, the 2-norcaranols were converted to 4-cycloheptenol, and

\* Corrected for isomerization under the reaction conditions and for the S<sub>N</sub>2 reaction.

bicyclo[3.1.0]hexane-6-methanol was completely converted to *trans*-2-vinylcyclopentanol. The compounds were, however, stable under the reaction conditions when a slight excess of base was added to the solvent. When this was done, the S<sub>N</sub>2 product, *endo*-6-bicyclo[3.1.1]heptanol, increased in amount.

It is possible to correct the observed data to take into account the isomerization reactions, making only the assumption that most of the cycloheptenyl acetate found in the acetolysis experiments arose from the norcaranyl acetates. This does not appear unreasonable in view of the results of the ethanolysis experiments. The corrected data are included in Table II.

Having presented the experimental data, we may now consider their significance. The *endo* isomer I is over a million times as reactive as the *exo* isomer II, indicating

that the rate acceleration characteristic of cyclobutyl derivatives requires that the leaving group occupy the pseudo equatorial position.<sup>6</sup> This conclusion had also been reached in our previous study of the 5-bicyclo[2.1.1]hexyl tosylates.<sup>7</sup>

A comparison of the kinetic data for acetic acid and for aqueous ethanol permits an estimation of the Winstein *m* and *N* values.<sup>7</sup> The *Y* value for 97.7% ethanol corresponds to that for glacial acetic acid. For the solvolysis of I, *m* was 0.56 and *N* was 0.66; whereas for II, *m* was 0.59 and *N* was 0.19. The last value is based on *Y* values determined at 25° whereas the rates of reaction were measured at 120°. The unusually low value of *N* is probably a result of not using *Y* values for 120°. The low values of *N* demonstrate that the reactions are limiting solvolyses, and the values of *m* are of a reasonable magnitude for such a process.

It is of interest to try to relate the rates of solvolysis with those of other compounds. At first, it appeared to us that 7-norbornyl derivatives would provide an adequate model in view of the similarity in structure.

It is generally recognized that there is a correlation between the C-C-C bond angle at the reaction site and the rate of solvolysis.<sup>8</sup> The angle for 7-norbornyl derivatives is 94°,<sup>9</sup> whereas that for bicyclo[3.1.1]heptyl derivatives must be less than 88°. <sup>10</sup> Thus, on this basis one might expect the latter to react more slowly than 7-norbornyl.

However, Brown has suggested that 7-norbornyl derivatives may for some reason be abnormal, since the rate of solvolysis of the tosylate is less than that of any other tosylate which has been studied, and since the rate of borohydride reduction of 7-norbornanone is greater than that of any other ketone which has been studied.<sup>11</sup> We may ask if there should be any structural factor which would lead to anomalous rates of reaction.

The important factor in these reactions is the *difference* in destabilization due to bond angle deformation between the tetrahedral and trigonal structures. Here, 7-norbornyl derivatives would be anticipated to be significantly different from monocyclic compounds. With cyclobutyl derivatives, for example, the tetrahedral structure has a bond angle<sup>4</sup> of about 87.8°, whereas the trigonal structure (cyclobutanone)<sup>12</sup> has an angle of

(6) Cyclobutane deviates from planarity by 35° (P. N. Skancke, Thesis, Oslo, 1960) leading to positions for substituents which are analogous to axial and equatorial positions of a cyclohexane ring.

(12) A. Bauder, F. Tank, and H. H. Günthard, *Helv. Chim. Acta*, **46**, 1453 (1963).

Figure 1. Relationship between rates of solvolysis and rates of borohydride reduction of the corresponding ketones. The solid line joins cyclopentyl with 7-norbornyl; the dashed line indicates the results with the cyclobutyl derivatives.

10.5°. Thus, the angle has increased significantly on going to the ketone, relieving some of the strain associated with the formation of a trigonal center. With norbornyl derivatives, however, the angle at the methylene bridge is constrained by the two-carbon wings and probably cannot change significantly on going from the alcohol to the ketone. Thus, despite the larger angles in 7-norbornanol and 7-norbornanone as compared to cyclobutanol and cyclobutanone, the increase in strain is probably greater for the former than for the latter.

The bicyclo[*n*.1.1]alkane derivatives would be expected to be intermediate in strain increase between cyclobutyl and 7-norbornyl compounds. This postulate could be tested if the heats of hydrogenation of the ketones to the alcohols were known. Unfortunately, these values are not as yet available. As a result, we have adopted the suggestion of Brown and Muzzio<sup>11</sup> that the rates of borohydride reduction of the ketones provide a model for the effect of converting a tetrahedral center to trigonal. The rate of reduction of bicyclo[3.1.1]heptanone-6 was determined giving a rate constant of  $1.4 \times 10^{-1} \text{ sec}^{-1}$  at 0°. As expected, the rate is between those for cyclobutanone and 7-norbornanone. The reaction led to 97.5% of *endo*-5-bicyclo[3.1.1]heptanol and 2.5% of *exo*-6-bicyclo[3.1.1]heptanol, giving the partial rate factors for *endo* and *exo* attack of  $3.5 \times 10^{-3}$  and  $1.5 \times 10^{-1} \text{ sec}^{-1}$ , respectively. The data required for a correlation with rates of solvolysis are summarized in Table III.

The rates of acetolysis are compared with the rates of borohydride reduction in Figure 1. Brown and Muzzio<sup>11</sup> have suggested that a line drawn through 7-norbornyl and cyclopentyl "would provide a reasonably satisfactory locus" for most of the compounds they examined. Such a line is drawn in the figure; the deviations ( $\pm 2$  log units) for cyclohexyl and cycloheptyl

Table III. Rates of Acetolysis and Borohydride Reduction

Ring	Solvolysis $k$ , 25°	$k_{\text{rel}}$	Reduction <sup>a</sup> $k$ , 0°
Cyclobutyl	$3.0 \times 10^{-3}$	27 <sup>b</sup>	$1.33 \times 10^{-3}$ *
Bicyclo[3.1.1]heptyl			
<i>exo</i> -6	$1.0 \times 10^{-3}$	0.021	$1.5 \times 10^{-1}$
<i>endo</i> -6	$4.44 \times 10^{-3}$	91,000	$3.5 \times 10^{-3}$
Norbornyl-7		$10^{-7}$ *	$7.5 \times 10^{-1}$ /
Cyclohexyl	$4.88 \times 10^{-3}$	1.00 <sup>d</sup>	$8.1 \times 10^{-3}$ *
Cyclopentyl	$1.58 \times 10^{-3}$	32.4 <sup>d</sup>	$3.5 \times 10^{-4}$ *

\* Partial rate factors. <sup>b</sup> J. D. Roberts and V. C. Chambers, *J. Am. Chem. Soc.*, **73**, 5034 (1951); H. C. Brown and G. Ham, *ibid.*, **78**, 2735 (1956). <sup>c</sup> S. Winstein, M. Shatavsky, C. Norton, and R. B. Woodward, *ibid.*, **77**, 4183 (1955). <sup>d</sup> S. Winstein, B. K. Morse, E. Grunwald, H. W. Jones, J. Corse, D. Trifan, and H. Marshall, *ibid.*, **74**, 1127 (1952). <sup>e</sup> H. C. Brown and K. Ichikawa, *Tetrahedron*, **1**, 221 (1957). <sup>f</sup> H. C. Brown and J. Muzzio, *J. Am. Chem. Soc.*, **88**, 2811 (1966).

derivatives perhaps suggest the uncertainty inherent in the correlation.

The three species of present interest, *endo*-6-bicyclo[3.1.1]heptyl, cyclobutyl, and *exo*-6-bicyclo[3.1.1]heptyl have acetolysis rates which are greater than expected by 6.0, 4.3, and 3.3 log units, respectively. Thus, using Brown's criterion, all appear to undergo solvolysis at accelerated rates.

The magnitude of the rate acceleration for cyclobutyl is in accord with other data. It has been found that the replacement of the  $\alpha$ -hydrogen by methyl in secondary alcohol derivatives normally produces a rate increase by a factor of about  $5 \times 10^4$ .<sup>13</sup> In the case of cyclobutyl, methyl substitution increases the rate by only a factor of about  $10^3$ .<sup>14</sup> If there were no special stabilization of the tertiary derivatives, the rate acceleration for cyclobutyl itself would be  $\sim 5 \times 10^3$ . This, of course, is a minimum value since 1-methylcyclobutyl derivatives may also react at a somewhat increased rate.<sup>15</sup>

The very large rate acceleration observed with *endo*-6-bicyclo[3.1.1]heptyl tosylate indicates a bridged activated complex. One may write the structure XIII and ask whether this represents the activated complex for a rearrangement to a more stable ion XIV, or whether it is an intermediate in the reaction and is stabilized by virtue of electron delocalization.

The 2-norcaranyl derivatives are very reactive in solvolytic reactions suggesting that the ion XIV is probably well stabilized in the fashion of cyclopropylcarbinyl cations.<sup>16</sup> The stabilization is particularly

(13) H. C. Brown and M.-H. Rei, *J. Am. Chem. Soc.*, **86**, 5008 (1964).  
(14) H. C. Brown and M. Borkowski, *ibid.*, **74**, 1894 (1952); J. D. Roberts and V. C. Chambers, *ibid.*, **73**, 5034 (1951).

(15) The correlation of acetolysis rates with carbonyl frequencies<sup>19</sup> does not appear to be particularly useful with cyclobutyl derivatives because of the lack of correlation of vibrational frequency with bond angle. Thus: cyclobutanone, 1791  $\text{cm}^{-1}$ ; 6-methylbicyclo[3.2.0]heptan-6-one, 1776  $\text{cm}^{-1}$ ; bicyclo[3.1.1]heptan-6-one, 1775  $\text{cm}^{-1}$ .

(16) (a) Cyclopropylcarbinyl intermediates: Wiberg and Ashe, see ref 4; P. von R. Schleyer and G. van Dine, *J. Am. Chem. Soc.*, **88**, 2321 (1966). (b) Stable cyclopropylcarbinyl ions: N. Deno, H. G. Richey, Jr., J. S. Liu, J. D. Hodge, J. J. Houser, and M. J. Wisotsky, *ibid.*, **84**, 2016 (1962); C. V. Pittman and G. Olah, *ibid.*, **87**, 2998 (1965); N. C. Deno, J. S. Liu, J. O. Turner, O. N. Lincoln, and R. E. Fruit, *ibid.*, **87**, 3000 (1965).

favorable since XIV is both cyclopropylcarbanyl and secondary. Since little thermochemical evidence is available concerning the relative energies of the classical cyclobutyl and the cyclopropylcarbanyl cations, it is not possible to estimate if the observed effect can be rationalized in terms of such a driving force. If the rate acceleration for *endo*-6-bicyclo[3.1.1]heptyl tosylate is taken as  $10^6$ , this corresponds to a stabilization of the activated complex by about 8.3 kcal/mole. The driving force would have to be greater than this amount since the driving force cannot be fully realized in the activated complex.

One possible way in which to obtain evidence dealing with the above question is to examine the possibility of trapping an intermediate using an ion in solution. In some cases, this has been accomplished using halide ion,<sup>17</sup> azide ion,<sup>18</sup> and methoxide ion.<sup>19</sup> An attempt was made to capture an intermediate ion using azide ion in acetic acid, and chloride ion in acetone. No chloride or azide corresponding to I was obtained<sup>20</sup> and olefin was the major product in acetone solution. Thus, the question remains unresolved at the present time. We shall, however, return to this question at a later time.

The solvolytic behavior of the *exo*-tosylate II is also of some interest in view of its apparent higher than expected reactivity. The products of the reaction may be derived *via* a series of carbonium ion reactions.

The carbon participation path, a, might be expected to give a modest rate acceleration since a 1,3-bridged cyclobutane is probably somewhat destabilized in comparison to a 1,2-bridged cyclobutane.<sup>21</sup> In the absence of thermochemical data, it is difficult to estimate the magnitude of the possible rate factor.

(19) H. Tanida, T. Teruji, and T. Irie, *ibid.*, **88**, 864 (1966).

(20) See, however, the reaction of *endo*-5-bicyclo[2.1.1]hexyl tosylate with chloride ion<sup>4</sup> in which unrearranged *endo*-chloride was the major product.

(21) This conclusion is not at all certain and is in the process of being tested. If the conclusion is incorrect, there would be no apparent driving force for rearrangement to XV.

The products of the reaction are, however, not in accord with the above formulation. First, the acetolyses of *exo*- and *endo*-bicyclo[3.2.0]heptyl-6 tosylates have been investigated<sup>22</sup> and neither gives bicyclo[3.2.0]heptyl-6 acetate or 7-norbornyl acetate as a product. However, both are formed in the present case. It seems likely that they are not formed *via* the 6-bicyclo[3.2.0]heptyl cation. Second, it is difficult to see why the product composition should be essentially unchanged on going from acetic acid to aqueous ethanol as solvent if the reaction involves a series of rearrangement steps. In these cases, one usually intercepts the ions at an earlier stage with the more nucleophilic aqueous ethanol as compared to acetic acid.

The simplest explanation for the rate acceleration and for the solvolysis products suggests that the products are derived from one principal intermediate which is stabilized in part by electron delocalization and in part by some strain relief resulting from the longer bonds in the "nonclassical" intermediate. The reactions may be formulated as in Scheme II. It can be seen that this intermediate provides a reasonable path for the formation of both bicyclo[3.2.0]heptyl-6 and 7-norbornyl derivatives. We do not consider that the data are such that they force one to accept a "nonclassical" intermediate. However, such an intermediate provides a simple, economical explanation for all of the data.

## Experimental Section

**Acetolysis of *endo*-Bicyclo[3.1.1]heptyl-6 Tosylate.** Into a set of about 15 test tubes was accurately measured increasing amounts of standard sodium acetate in acetic acid. The final volume in each was adjusted to 10 ml with anhydrous acetic acid. Several drops of brom phenol blue in acetic acid was added to each tube as an indicator. The test tubes were stoppered, placed in a constant temperature bath, and allowed to equilibrate for 15 min. *endo*-Bicyclo[3.1.1]heptane-6 tosylate (300 mg) was dissolved in approximately 3 ml of carbon tetrachloride. A 200- $\mu$ l portion of this solution was transferred with stirring to a test tube using a Hamilton 250- $\mu$ l syringe. Zero time was taken at the completion of addition, and the time for the indicator change was recorded. The process was repeated for each test tube, covering a range of 10–90% reaction. This method eliminated the problem of the time required to dissolve the tosylate in the reaction solvent, and permitted reactions with a half-life as short as 30 sec to be studied.

**Ethanolsolysis of *endo*-Bicyclo[3.1.1]heptyl-6 Tosylate.** Two ethanol-water mixtures were prepared having 79.95 and 95.00% ethanol by volume (the former had a density of 0.84930 at 25.0°; and the latter had 0.80321). The experiments were carried out as described above except that the base solution was prepared by dissolving sodium in the alcohol-water mixture and standardizing against hydrochloric acid solution by titration.

**Acetolysis of *exo*-Bicyclo[3.1.1]heptyl-6 Tosylate.** Solutions of the tosylate were prepared by weighing the tosylate into a volumetric flask and diluting to 50 ml with glacial acetic acid containing approximately 1% acetic anhydride and sufficient sodium acetate to neutralize the *p*-toluenesulfonic acid formed. Portions (3.3 ml) of the solution were placed in ampoules, and the ampoules were sealed. The ampoules were placed in a constant temperature water bath and were allowed to equilibrate. They were removed at known times, cooled rapidly to room temperature, and broken open; 3 ml of the solution was removed for titration with standard sodium acetate in glacial acetic acid. Brom phenol blue was used as the indicator.

**Ethanolsolysis of *exo*-Bicyclo[3.1.1]heptyl-6 Tosylate.** The ethanolsolysis was carried out in the same manner as the acetolysis runs using 79.95 and 97.75% ethanol. The latter had a density of 0.79371 at 25°.

(22) F. F. Nelson, Ph.D. Thesis, University of Wisconsin, 1960.

**Acetolysis Studies.** a. *endo*-Bicyclo[3.1.1]heptyl-6 Tosylate. A solution of 0.5 g of the tosylate (containing 20–30% of the *exo* isomer) in acetic acid containing a small excess of sodium acetate was allowed to stand for 15 min at room temperature. The mixture was diluted with an equal volume of water and extracted with portions of pentane. The pentane solution was washed with 2.5% sodium bicarbonate solution, and again with water. After drying, distillation gave 150 mg of a clear liquid, and residue. The latter was shown by nmr to be *exo*-bicyclo[3.1.1]heptyl-6 tosylate. The distillate was examined by vpc using a Carbowax column at 148°. The first component (19.5 min) was 4-acetoxycycloheptene, and the second component (21.5 min shoulder at 22.5 min) was a 4:1 mixture of *endo*- and *exo*-norbornyl acetates. Both components were identified by comparison with authentic samples.

The acetolysis was carried out in the absence of acetate ion, and amount of 4-acetoxycycloheptene increased at the expense of the norbornyl acetates.

**Ethanolysis of *endo*-Bicyclo[3.1.1]heptyl-6 Tosylate.** A solution of 0.6 g of the tosylate in 50 ml of 80% ethanol containing 120 mg of sodium acetate was allowed to stand for 8 min at room temperature. The reaction mixture was worked up as described above, and the products of ethers and alcohols were dissolved in pyridine and cooled to 0°. To this solution was added 2.0 g of acetyl chloride. After 10 minutes, 6 ml of water was added, and the mixture was extracted with two 20-ml. portions of pentane. The pentane solution was washed with two portions of dilute hydrochloric acid, two portions of water, and two portions of 5% sodium bicarbonate solution. After drying, the pentane was removed, and distillation of the residue gave 0.2 g of a mixture of ethers and acetates. Vpc analysis indicated that the acetate products were the same as from acetolysis. The ether:acetate ratio was 88:12.

***exo*-Bicyclo[3.1.1]heptyl-6 Tosylate.** A solution of 2.0 g of the tosylate in 160 ml of anhydrous acetic acid containing 0.027 g of sodium acetate was heated in a sealed flask at 120° for 1 hr. It was cooled, diluted with 200 ml of water, and extracted with three 175-ml portions of pentane. The pentane solution was washed with three 250-ml portions of 2.5% sodium bicarbonate solution and with water. After drying, distillation of the solvent

gave 1.0 g of products. Vpc analysis using a Carbowax column at 140° indicated four components. The first component (8 min, 17%) was *trans*-2-vinylcyclopentyl acetate;<sup>22</sup> the second (10 min, 7%) was 7-norbornyl acetate; the third (11 min, 11%) was a mixture of *exo*-bicyclo[3.2.0]heptyl-6 acetate and *exo*-norbornyl acetate; and the fourth (14 min, 65%) was a mixture of 4-acetoxycycloheptene<sup>23</sup> and *exo*-bicyclo[3.1.0]hexane-6-methyl acetate.<sup>23</sup> The last mixture could be separated using an XF-1150 column. All components were identified by comparison with authentic samples.

**d. Ethanolysis of *exo*-Bicyclo[3.1.1]heptyl-6 Tosylate.** The reaction was carried out essentially as described above, and the products were converted to acetates using acetyl chloride in pyridine. The ratio of ethers to acetates was 30:70. The acetates were the same as found in the acetolysis, but in a different ratio.

**Bicyclo[3.1.1]heptanone-6.** A solution of 5 g of *exo*-bicyclo[3.1.1]heptanol-6, 11.2 g of aluminum *t*-butoxide, and 19.1 g of benzoquinone in 570 ml of anhydrous ether was heated to reflux for 12.5 hr. The ether was removed by distillation, and the volatile material was collected at 0.3 mm. The latter was separated by vpc using a 1/8 in. DEGS column at 140°. The ketone with a retention time of 8 min was collected giving 1.3 g (26%). It had an infrared carbonyl band at 1775 cm<sup>-1</sup>.

**Reduction of Bicyclo[3.1.1]heptanone-6.** The rate of reduction by sodium borohydride was determined at 0° in isopropyl alcohol solution as described by Brown and Muzzio.<sup>11</sup> The concentration of ketone was 0.00506 M, and of borohydride 0.00190 M. Assuming a 1:4 stoichiometry, good second-order kinetics were observed with  $k = 1.4 \times 10^{-1}$  sec.

The product of the reduction was converted to acetates using pyridine and acetyl chloride. The acetates were isolated by vpc using a DEGS column at 140° (retention time 7.5 min). The nmr spectrum of the mixture indicated a strong triplet at  $\tau$  5.31 for the  $-\text{CHOAc}$  proton of the *endo* isomer and a weak doublet at  $\tau$  5.69 for the corresponding proton of the *exo* isomer.<sup>8</sup> The ratio of the areas of the two bands indicated 97.5% *endo* and 2.5% *exo* acetates.

(23) An authentic sample was kindly supplied by Dr. A. J. Ashe.

# Aminolysis of Esters. I. Kinetics and Mechanism in Anhydrous Dioxane<sup>1</sup>

A. Sami A. S. Shawali<sup>2</sup> and Sydney S. Biechler<sup>3</sup>

Contribution from the Department of Chemistry, Lowell Technological Institute, Lowell, Massachusetts 01854. Received February 4, 1967

**Abstract:** The kinetics of aminolysis of 11 phenyl esters by various amines have been studied spectrophotometrically under pseudo-first-order conditions in anhydrous *p*-dioxane. The following relationships were found:  $k_{\text{obsd}} = k_2(\text{amine}) + k_3(\text{amine})^2$  for the reaction of phenyl dichloroacetate with *n*-butylamine and 3-methoxy-*n*-propylamine, and for the reaction of phenyl difluoroacetate with *n*-butylamine;  $k_{\text{obsd}} = k_2(\text{amine})$  for the reaction of phenyl dichloroacetate with *N*-methyl-*n*-butylamine, piperidine, *N,N*-dimethyl-1,3-propanediamine, and *N,N,N'*-trimethyl-1,3-propanediamine, and for the reaction of phenyl difluoroacetate with piperidine and *N*-methyl-*n*-butylamine;  $k_{\text{obsd}} = k_2(\text{amine}) + k_3(\text{amine}) + k_3'(\text{amine})(\text{Et}_3\text{N})$  for the reaction of phenyl dichloroacetate and *n*-butylamine where catalytic amounts of triethylamine were added. A series of reactions in cyclohexane was performed, and only third-order kinetics were detected. Rate constants for the reaction of ten different aliphatic esters with *n*-butylamine were correlated by the Taft equation,  $\log(k/k_0) = \rho^*\sigma^* + \delta E_s$ .

Although much information is available in the literature concerning the aminolysis and ammonolysis of esters, essentially none exists in aprotic solvent systems. Reactions of this type have been extensively investigated in aqueous solution.<sup>4</sup> Organic solvents have been used by other investigators, but these have been either alcohols,<sup>5</sup> glycols, dioxane-water, or dioxane-alcohol.<sup>6</sup>

The present study undertakes kinetic studies of this reaction in anhydrous dioxane, in order to establish the order of reaction in this solvent, and to determine whether the same observation of general base catalysis with primary amines, such as has been well established in aqueous solution,<sup>4a</sup> is obtained. It was also desired to examine the effect of structure of the acyl portion of the ester, in the hope of shedding more light on the mechanism of this reaction in aprotic solvents.

## Experimental Section

**Materials.** *p*-Dioxane was Matheson Coleman and Bell Spectroquality reagent grade solvent. Its purity was checked by infrared, ultraviolet, and vapor phase chromatographic analyses.

Difluoroacetic acid was purchased from K and K Laboratories; distillation at atmospheric pressure gave a distillate of boiling range 125–134°. This corresponds to the boiling point of a 10% water–acid azeotrope.<sup>7</sup>

Sodium phenolate was prepared by reaction of phenol (Fisher Scientific Co., purified by distillation) with sodium in anhydrous benzene.

**Amines.** *n*-Butylamine, *N*-methyl-*n*-butylamine, 3-methoxy-*n*-propylamine, and *N,N*-dimethyl-1,3-propanediamine were purchased from Matheson Coleman and Bell. Piperidine and triethylamine were obtained from Eastman Organic Chemical Co. The amines were purified by storing overnight over sodium hy-

dride pellets and then distilling at atmospheric pressure from fresh sodium hydroxide pellets using a 15-in. Vigreux column. The fraction having a constant boiling point was collected and stored in an amber glass bottle over fresh sodium hydroxide pellets.

*N,N,N'*-Trimethyl-1,3-propanediamine was prepared from 3-chloro-*N,N*-dimethyl-*n*-propylamine hydrochloride (Matheson Coleman and Bell), 20 g (0.11 mole), which was dissolved in 100 ml of distilled water. A solution of 40% aqueous methylamine (Matheson Coleman and Bell), 77.5 g (ca. 1.1 moles), was added, and the mixture was refluxed gently for 6 hr. The cooled reaction mixture was treated with solid potassium hydroxide until some solid remained undissolved. The amine layer which separated was removed, the aqueous layer was extracted several times with ether, and the ether extracts were added to the diamine. The ether solution was washed with saturated sodium hydroxide solution, dried over anhydrous sodium sulfate, and the ether removed on a water bath. The residue was distilled through a 10-in. Vigreux column to give 7.0 g (55% yield) of colorless liquid product.

The degree of purity of each amine was determined by acid–base titration and was checked by vapor phase chromatographic analysis. In the former method, a known weight of the amine dissolved in a known excess of standard hydrochloric acid was titrated against a standard solution of sodium hydroxide using methyl red (pH 4.4–6.2) as an indicator. In the latter method, an F & M Model 720 gas chromatograph with a 3-ft Carbowax column was used. For all amines, a clean single peak was obtained, indicating almost 100% purity.

Refractive indices, boiling points, and infrared spectra were also determined for the amines. A common absorption band between 2900 and 3000 cm<sup>−1</sup> corresponding to methyl and methylene stretch was observed. The physical constants and degree of purity of the individual amines are listed as follows: *n*-butylamine, bp 77–77.5°, *n*<sub>D</sub><sup>20</sup> 1.3976, 99.9% pure (lit.<sup>7</sup> bp 77°; *n*<sub>D</sub><sup>20</sup> 1.4010); *n*-methyl-*n*-butylamine, bp 90–91°, *n*<sub>D</sub><sup>20</sup> 1.3997, 100.0% pure (lit.<sup>7</sup> bp 90–99°, *n*<sub>D</sub><sup>20</sup> 1.4018); 3-methoxy-*n*-propylamine, bp 116–118°, *n*<sub>D</sub><sup>20</sup> 1.4315, 100.0% pure (lit.<sup>8</sup> bp 118°, *n*<sub>D</sub><sup>20</sup> 1.4182); *N,N*-dimethyl-1,3-propanediamine, bp 132–133°, *n*<sub>D</sub><sup>20</sup> 1.4315, 99.8% (lit.<sup>9</sup> bp 130–133°); piperidine, bp 104–105.5°, *n*<sub>D</sub><sup>20</sup> 1.4500, 99.9% pure (lit.<sup>7</sup> bp 106°, *n*<sub>D</sub><sup>20</sup> 1.4530); triethylamine, bp 88–89°, *n*<sub>D</sub><sup>20</sup> 1.4003, 99.9% pure (lit.<sup>10</sup> bp 89–90° *n*<sub>D</sub><sup>20</sup> 1.4003); and *N,N,N'*-trimethyl-1,3-propanediamine, bp 140–143°, *n*<sub>D</sub><sup>20</sup> 1.4275, 99.8% pure (lit.<sup>11</sup> bp 140–142°).

**Esters.** Phenyl Dichloroacetate. Dichloroacetyl chloride (prepared from Matheson Coleman and Bell dichloroacetic acid by the method of Brown<sup>12</sup>), 14.4 g (0.098 mole), and 7.8 g (0.083 mole) of phenol were placed in a 150-ml, ground-joint, round-

bottomed flask with a water condenser, and the mixture was refluxed until evolution of HCl gas ceased (about 5 hr). The mixture was dissolved in excess hot petroleum ether and filtered. The white solid ester which crystallized on cooling the filtrate was recrystallized from petroleum ether to give 13.4 g (80% yield) of the crystalline solid, melting at 48–49° (lit.<sup>13</sup> mp 38.5–49.5°). The infrared spectrum of an emulsion of this solid in Nujol showed absorption bands at 1775 (C=O stretch), 1600 (C=C stretch), 1497 (aromatic H—C=C stretch), and 1200–1 cm<sup>-1</sup> (C—C=C stretch).

**Phenyl Difluoroacetate.** Into a 200-ml, three-necked, round-bottomed flask fitted with condenser, dropping funnel, and thermometer, was introduced 8 g (0.07 mole) of sodium phenolate. To this, 7.3 g of the water–acid azeotrope (0.067 mole of difluoroacetic acid) was added. The mixture was stirred with a magnetic stirrer while cooling to 10° in a crushed ice–salt bath. From the dropping funnel, 5.5 g (0.036 mole) of phosphorus oxychloride was added portionwise to maintain the temperature at 10° (the excess POCl<sub>3</sub> was used to consume the water present in the azeotrope). After the addition was complete, the reaction mixture was allowed to warm to room temperature and heat was gently applied while stirring until evolution of HCl gas ceased. After 2 hr, the flask was cooled, and the reaction mixture was extracted with ether. After removal of ether with a water aspirator, the liquid residue was distilled (23 mm), and the fraction having bp 88–92° was collected and refractionated twice to give 7.0 g of a colorless liquid, bp 90–91° (23 mm),  $n_D^{20}$  1.4617,  $d_4^{21.7}$  1.262 g/cc. *Anal.* Calcd for C<sub>8</sub>H<sub>6</sub>F<sub>2</sub>O<sub>2</sub>: C, 55.81. Found: C, 55.6. The infrared spectrum of a liquid sample showed absorption bands at 1790 (C=O stretch), 1600 (C=C stretch), 1500 (aromatic H—C=C stretch), 1215 (O—C=C stretch), and 1115 cm<sup>-1</sup> (F<sub>2</sub>C—) (not reported in the literature).

**Phenyl Trichloroacetate.** Into a 1-l. three-necked flask fitted with a stirrer, condenser, and dropping funnel, was placed 23 g (0.2 mole) of sodium phenolate and 300 ml of dry benzene. From the separatory funnel, 37 g (0.2 mole) of freshly prepared trichloroacetyl chloride (prepared by the method of Brown<sup>11</sup>) was added with stirring. After the addition was complete, the reaction mixture was stirred for 45 min. The sodium chloride which separated was removed by filtration and the solvent removed on a rotary evaporator. The residue was distilled (1.0 mm) and the fraction boiling at 98–101° was collected and redistilled. The final product was obtained at 100–101° (1.0 mm) [lit.<sup>13</sup> 122° (14 mm),  $n_D^{20}$  1.5232]. The yield was 13.5 g (28.7%).

**Phenyl Chloroacetate.** This was prepared in the same manner as phenyl trichloroacetate. The solid obtained had mp 40–41° [lit.<sup>13</sup> bp 140–141° (31 mm)].

**Phenyl Methoxyacetate.** This was prepared by the same method as phenyl trichloroacetate, except that phenol was used instead of sodium phenolate. The ester, 11.6 g (71%), had bp 127–128° (13 mm),  $n_D^{20}$  1.5000,  $d_4^{21.7}$  1.11 g/cc. *Anal.* Calcd for C<sub>9</sub>H<sub>10</sub>O<sub>3</sub>: C, 65.0. Found: C, 65.3. This compound was not reported in the literature.

**Phenyl Formate.** This was prepared by the method of Buzas, Engell, and Freon.<sup>14</sup> The final product was obtained in 6.9-g (57%) yield and had bp 62–64° (8 mm),  $n_D^{20}$  1.5055 [lit.<sup>15</sup> bp 178–178.5° (8 mm),  $n_D^{15}$  1.5094].

**Phenyl Cyanoacetate.** This was prepared by the method of Ziegler and co-workers<sup>16</sup> except that sodium phenolate was used instead of phenol. The white crystalline product was obtained in 5-g (31%) yield and had mp 39–40° (lit.<sup>16</sup> mp 41°).

**Phenyl Phenylacetate.** This was prepared according to the Schotten–Baumann reaction.<sup>17</sup> The ester, 4.5 g (60% yield), was obtained as white needle-like crystals, mp 39.5–40.5° (lit.<sup>18</sup> 39–40°).

**Phenyl Acetate.** This was prepared by the method of Chattaw<sup>19</sup> from acetic anhydride and phenol. The product was a colorless liquid, bp 72–74° (11 mm),  $n_D^{20}$  1.5020 [lit.<sup>19</sup> bp 78° (10 mm),  $n_D^{20}$  1.5030].

**Phenyl Propionate.** Into a 100-ml, round-bottomed flask was placed 0.1 mole of phenol in 35 ml of dry benzene. To this, 0.12

mole of propionyl chloride (prepared by the method of Brown<sup>11</sup>) and 1.2 g of magnesium metal were added. A condenser was added and the mixture refluxed on a water bath until evolution of hydrogen chloride ceased. The flask was cooled; 25 ml of ether was added, and the mixture filtered. The filtrate was extracted once with 5% aqueous sodium hydroxide and three times with 50-ml portions of cold water. After drying over sodium sulfate, and removal of solvent with a rotary evaporator, the residue was distilled under reduced pressure. The fraction boiling at 82–85° (2 mm) was collected and redistilled. The final product was obtained in 9-g (60%) yield and had bp 82–83°,  $n_D^{20}$  1.4952 [lit.<sup>20</sup> bp 98–99° (8 mm),  $n_D^{20}$  1.5003].

**Phenyl Pivalate.** This was prepared by the same method as phenyl propionate. The clear liquid product was obtained in 20-g (70%) yield and had bp 109–111° (21 mm),  $n_D^{20}$  1.4761 [lit.<sup>20</sup> bp 118–119° (35 mm)].

**Kinetics.** A Bausch and Lomb Spectronic 505 ultraviolet spectrophotometer with jacketed cell compartment was used for the kinetic measurements. Water at 25.5 ± 0.1° was circulated through the cell compartment by means of a constant-temperature bath unit, Haake Circulator Series F. The reactions were carried out in 1-cm, ground-glass-stoppered, fused silica absorption cells.

The reactions were followed by rate of appearance of the phenol peak at 274 mμ. The corresponding amides and esters showed no absorption in the 230–290-mμ region. Complete spectra taken for several mixtures of amide and phenol in *p*-dioxane corresponded to the spectra of pure phenol solutions having the same concentration of phenol. Also, complete spectra taken at the end of each kinetic run corresponded to the spectra of phenol solutions of the same concentration. Beer's law was found to be obeyed within the concentration and wavelength range employed.

Stock solutions of esters, usually about 10<sup>-3</sup> M, were prepared and the concentrations checked by comparing the optical density with that calculated from the Beer's law relationship at 274 mμ. Stock amine solutions were prepared and the concentration determined by acid–base titration. Appropriate concentrations of amine and ester were prepared by dilution of the stock solutions with *p*-dioxane. All ester concentrations were 5.00 × 10<sup>-4</sup> M.

Reactions were followed to 90–99% completion, with at least 15 readings taken. For kinetic runs which could be completed in a day or less, the reactions were carried out in the absorption cells. For slower runs, the reactions were begun in 25-ml volumetric flasks. A sample was removed and placed in the cell in the instrument, and the cell was returned to the constant-temperature bath. The cell was allowed to remain in the instrument for the first day, frequent readings being taken. The solution in the cell was discarded and aliquots were removed from the flask for all subsequent readings.

The reference solution was that of dioxane containing an equal amine concentration to that being used in the particular run.

Comparison of the spectra of a completed reaction and a mock solution consisting of the phenol, amine, and amide in *p*-dioxane in the expected concentrations showed a consistency within 1–2% transmittance units. In all runs, at least a tenfold excess of amine over ester was used in order to obtain pseudo-first-order kinetics. Duplicate or triplicate runs were performed for each concentration, and readings taken in any single kinetic run covered a rate of 85% transmittance units.

**Stoichiometry and Isolation of Products.** Authentic samples of *N*-*n*-butyldichloroacetamide and of 1-difluoroacetyl piperidine were prepared by independent methods. Laboratory quantities of two reactions were carried out: (1) phenyl dichloroacetate with *n*-butylamine, (2) phenyl difluoroacetate with piperidine. The expected amides were obtained in about 70% yield and were identical in physical properties with the authentic samples.

**Results.** Pseudo-first-order kinetics were obtained for all runs. Reactions were followed to 90–99% completion with at least 15 points being taken, and good first-order plots of log ( $D - D_i$ ) against time were obtained as shown in Figure 1. In all kinetic runs the ester concentration was 5.0 × 10<sup>-4</sup> M. The average deviation from the mean value of the rate constant in duplicate or triplicate experiments was ± 5% or less.

For the reactions of primary amines with all esters except phenyl methoxyacetate, the following rate equation was obtained

$$k_1/(\text{amine}) = k_2 + k_3(\text{amine})$$

This is illustrated in Figure 2, where a plot of  $k_1/(\text{amine})$  against amine concentration gives a straight line.

Figure 1. Typical first-order plot for aminolysis of phenyl esters. Reaction of 0.180 *M* *N*-methyl-*n*-butylamine with phenyl dichloroacetate.

Figure 2. Plot of  $k_1/(\text{amine})$  against amine concentration for the reaction of phenyl dichloroacetate with *n*-butylamine in *p*-dioxane at 25.5°.

Simple second-order kinetics were found for the reactions of secondary amines and diamines with all esters, and for the reaction of phenyl methoxyacetate with *n*-butylamine, as shown in Figure 3, where a plot of  $k_1$  against amine concentration gives a linear relationship. That is

$$k_1 = k_2(\text{amine})$$

For the reaction between *n*-butylamine and phenyl dichloroacetate, with triethylamine added as a catalyst, the following relationship was found

$$k_1 = k_2(\text{amine}) + k_3(\text{amine})^2 + k_3(\text{Et}_3\text{N})(\text{amine})$$

Since in this series both the ester and *n*-butylamine concentrations were held constant and the triethylamine concentration varied, plots of  $k_1$  against triethylamine concentration were linear as shown in Figure 4. The calculated intercept of this plot, equal to  $k_2$ .

Figure 3. Simple second-order plot for the reaction of phenyl dichloroacetate with *N,N,N'*-trimethyl-1,3-propanediamine in *p*-dioxane at 25.5°.

Figure 4. Plot of  $k_1$  against triethylamine concentration for *n*-butylaminolysis of phenyl dichloroacetate in *p*-dioxane at 28.0°; *n*-BuNH<sub>2</sub> concentration is held constant (0.021 *M*).

(amine) +  $k_3(\text{amine})^2$  agrees within experimental precision with the experimentally determined pseudo-first-order rate constant for aminolysis of phenyl dichloroacetate by *n*-butylamine in the absence of triethylamine under the same conditions of temperature and *n*-butylamine concentration.

Values of  $k_2$ ,  $k_3$ , and  $k_3'$  were calculated by the method of least squares and are summarized in Tables I, II, and III.

In a series of experiments carried out in cyclohexane on the reaction of *n*-butylamine with phenyl dichloroacetate, only third-order kinetics were obtained, as shown in Figure 5, where no intercept was obtained from a plot of  $k_1/(\text{amine})$  against (amine).

The kinetic data for the series of esters excluding phenyl methoxyacetate was found to be correlated by the Taft equation of the type

$$\log (k/k_0) = \sigma^* \rho^* + \delta E_s^{21}$$

Both second- and third-order constants were correlated by this equation, as shown in Figures 6 and 7. Figure 8 shows the scatter obtained when a correlation of the type  $\log (k/k_0) = \sigma^* \rho^*$  was attempted; similar scatter was obtained from plots of  $\log (k/k_0)$  against  $E_s$ , log relative rate constants for alkaline specification of esters, and acid dissociation constants (Hammett-type plot).

The polar and steric susceptibility parameters for this series were as follows

	$\rho^*$	$\delta$
<i>k</i> <sub>2</sub>	+3.03	+1.08
<i>k</i> <sub>3</sub>	+2.14	+1.03

## Discussion

**Mechanism of Base Catalysis.** The disappearance of the second-order rate constant when cyclohexane is used as solvent seems to indicate that the second-order term obtained in the reaction of phenyl esters with *n*-butylamine represents a solvent-catalyzed term, rather than an uncatalyzed term. This suggests that the reaction of phenyl esters with secondary amines may proceed *via* a different mechanism than that with primary amines. In this paper, only the mechanism involving general base catalysis will be discussed.

Consistent with the observations are eq 1 and 2. In the first step, the intermediate II is pictured as forming by nucleophilic attack of nitrogen with simultaneous protonation of the carbonyl, in order to avoid the use of ionic intermediates, which are considered here

Figure 5. Plot of  $k_1/(\text{amine})$  against amine concentration for the reaction of phenyl dichloroacetate with *n*-butylamine in cyclohexane at 25.5°.

as having little importance since the reaction takes place in a solvent of low dielectric constant. Construction of Godfrey models has shown that this simultaneous bond formation is sterically and geometrically feasible.

In the second step, the intermediate is shown as losing phenol by protonation of phenoxy group by amine nitrogen, assisted by the base catalyst B. In this study, B could be another molecule of attacking amine, triethylamine, or the solvent, dioxane.

This stepwise scheme is, of course, kinetically indistinguishable from a concerted mechanism, as follows

Figure 6.

Figure 7.

Our data do not permit a distinction between the two alternatives at the present time; however, our

servations are consistent with the protonation of the phenoxy group by the amine hydrogen, rather than by the base catalyst. Catalysis by triethylamine, a tertiary amine, and the observation that base catalysis does not occur with secondary attacking amines, seem to substantiate this. Although the mechanism in aqueous solution may not be the same as that in dioxane, it is interesting that much of the literature data for aqueous solutions is consistent with this explanation. For example, in aminolysis of phenyl acetate, Jencks and co-workers found general base catalysis for the primary amines *n*-butylamine, hydroxylamine, glycine, and glycylglycine,<sup>22</sup> methylamine, ethylamine, and *n*-propylamine,<sup>23</sup> but not for the secondary amines piperidine and morpholine.<sup>22</sup> Bruice and co-workers<sup>23</sup> obtained no general base catalysis for three cyclic secondary amines. One notable exception is the observation of Jencks and Carriuolo<sup>22</sup> that general base catalysis does occur for the reaction of dimethylamine with phenyl acetate. This amine will be investigated in dioxane solution in this laboratory.

**Intramolecular Catalysis.** The observation of second-order kinetics without general base catalysis in the reactions of two diamines with phenyl esters in dioxane is in agreement with the results of Bruice and Willis<sup>24</sup> who found no general base catalysis for a series of diamines in aqueous solution. One may suggest an explanation in terms of intramolecular catalysis, as shown below

A reaction involving the intermediate VI might be expected to proceed more slowly than that involving VII since the pictured catalytic effect cannot operate in VI. In fact, the observation was made that the reaction of *N,N*-dimethyl-1,3-propanediamine with phenyl dichloroacetate had a rate constant 13 times as large as that for the reaction of *N,N,N'*-trimethyl-1,3-propanediamine with the same ester, as can be seen from the data in Table I.

An analogous explanation may be given to explain the lack of external base catalysis for phenyl methoxyacetate, where the methoxy group might act as the base, B, in the proposed mechanism. If one accepts the idea that dioxane may act as a base catalyst in this reaction, extrapolation to include the methoxy group is not too difficult. Again, a difference in rate constants by a factor of 13 (Table III) between the two amines, *n*-butylamine (the faster) and *N*-methyl-*n*-butylamine, is consistent with this, since in the latter the catalytic effect is not expected to operate.

**The Effect of Structure.** The probability of a coincidental fit to the Taft equation  $\log k/k_0 = \rho^*\sigma^* + \delta E_s$

Figure 8.

is very small, since the lack of generality of this equation is well established; indeed, only two other reaction series have been found to be correlated by this equation, *viz.*, the methanolysis of 1-menthyl esters<sup>25</sup> and the alkylation of amino acids by acetonitrile.<sup>26</sup> In the present study, a range of eight powers of 10 in the rate constants was covered, increasing the unlikelihood of a coincidental fit to the equation.

Comparison of the reaction parameters of the solvent-catalyzed reaction and the amine-catalyzed reaction shows that the reaction with the stronger base is much more susceptible to polar requirements than is the solvent-catalyzed reaction. On the other hand, the steric requirements appear to be independent of the nature of the catalyzing base. This can also be seen by examination of the rate constant ratios,  $k_3/k_2$ , shown in Table I. The ratios are large for those substituents having large electron-withdrawing properties, and decrease to around one for the alkyl substituents.

These observations may be reconciled with the proposed mechanism as follows. If the decomposition of the intermediate is considered to be rate determining, then this will be made more difficult with increased polar requirements of the acyl substituent. The base-catalyzed decomposition of the intermediate, then, could be considered to require a much stronger base to remove the phenol than would be needed for compounds having substituents of lesser polarity. The first step, on the other hand, would be facilitated by electron-withdrawing substituents, and the larger over-all rate for these compounds may be considered to be due to a greater "piling up" of the intermediate than occurs with compounds having substituents of lesser polarity.

Work is now in progress to investigate the effect of different donor groups in the acyl portion of the ester, both to seek a Brønsted relationship if this be base catalysis, and to determine the effect of proximity to the reaction center by addition of methylene groups between

## A New Approach to the Synthesis of $\alpha$ -Hydroxy- $\beta$ -diketones and $\gamma$ -Bromo- $\alpha$ -hydroxy- $\beta$ -diketones and Their Phosphate Esters

Fausto Ramirez,<sup>1</sup> S. B. Bhatia, and C. P. Smith

Contribution from the Department of Chemistry of the State University of New York at Stony Brook, Stony Brook, New York 11790.

Received February 10, 1967

**Abstract:** 2,2,2-Trimethoxy-4,5-dimethyl-1,3,2-dioxaphospholene, made from trimethyl phosphite and biacetyl, reacted with ketene,  $\text{CH}_2=\text{C}=\text{O}$ , and gave 2,2,2-trimethoxy-4-methylene-5-acetyl-5-methyl-1,3,2-dioxaphospholane in over 90% yield. This phospholane was quantitatively converted by hydrogen chloride into the dimethyl phosphate ester of 3-methylpentan-3-ol-2,4-dione (diacetylmethylcarbinol). The phosphorus-free hydroxydiketone was made from the phospholane or the phosphate in boiling aqueous benzene. Bromination of the phospholane gave the dimethyl phosphate ester of 1-bromo-3-methylpentan-3-ol-2,4-dione.

The formation of a carbon-carbon single bond by the nucleophilic addition of a 2,2,2-trialkoxy-1,3,2-dioxaphospholene<sup>2</sup> (I) to a carbonyl function II was first reported in 1961.<sup>3</sup> This condensation reaction made available the new 2,2,2-trialkoxy-1,3,2-dioxaphospholanes<sup>4</sup> (III).

The phospholanes III could be transformed into cyclic and open-chain phosphate esters, and into phosphorus-free polyoxygenated functions.<sup>5</sup> Some of the phospholanes were also capable of undergoing molecular rearrangements when heated in methanol solution.<sup>4,6</sup>

This paper describes the condensation of a phospholene I with ketene,<sup>7</sup> and discloses a new approach to the

synthesis of  $\alpha$ -hydroxy- $\beta$ -diketones and  $\gamma$ -bromo- $\alpha$ -hydroxy- $\beta$ -diketones and their phosphate esters.

### Results

**Reaction of Ketene with the Trimethyl Biacetylphosphite 1:1 Adduct IV.** The reaction of ketene V with 2,2,2-trimethoxy-4,5-dimethyl-1,3,2-dioxaphospholene (IV) took place at 0° in methylene chloride solution. The product was 2,2,2-trimethoxy-4-methylene-5-acetyl-5-methyl-1,3,2-dioxaphospholane (VI) isolated in 90% yield.

The phospholane VI probably arose in a concerted nucleophilic addition of the phospholene IV to the ketene V without the formation of an intermediate dipolar ion like VII.<sup>8</sup> However, the transient formation of undetectably small amounts of VII cannot be excluded.

The pentaoxyphosphorane VI was distinguished from the isomeric tetraoxyalkylphosphorane VIII on the basis of the following spectral data.

(7) While this work was in progress, A. J. Kirby [*Tetrahedron*, **22**, 3001 (1966)] published experiments involving the phospholene IV and carbon disulfide. Our studies of the reactions of IV, and of related phospholenes, with a number of systems having cumulated double bonds will be published in a separate communication.

) The  $P^{31}$  nmr shift,  $\delta P^{31}$ , of VI was very close to found for other related pentaalkoxyphosphoranes<sup>4,9</sup> type III. On the other hand, the tetraalkoxyalkylphosphorane IX gave a signal at a much lower magnetic field.<sup>10</sup>

2) The  $H^1$  nmr spectrum of VI, examined at 60 and Mc/sec, had one-proton signals at  $\tau$  5.80 and 6.21. h signals consisted of doublets of doublets. The coupling between the two vinyl protons was  $J_{HH} = 1.9$ . One of the hydrogen-phosphorus couplings was  $\sim 1.9$  cps and, therefore, the signal looked like a distorted triplet. The other  $J_{HP}$  value was approximately 1.4 cps. These values were in agreement with structure VI but not VIII. The three indistinguishable hydroxy groups gave one doublet at  $\tau$  6.40,  $J_{HP} = 13$  cps. The acetyl and the methyl protons were at  $\tau$  7.82 and 7.95, respectively.

3) The infrared spectrum of VI had the expected bands at 5.80 and 6.00  $\mu$  due to the acetyl and the enol phosphorane, respectively.<sup>11</sup>

**Reaction of the Phospholane VI with Hydrogen Chloride.** This reaction afforded the dimethyl phosphorane of 3-methylpentan-3-ol-2,4-dione (XI) in quantitative yield. Probably, a tetraalkoxyphosphonium chloride X was an intermediate.

The reaction can be considered as an alkylation of hydrogen chloride by the unsaturated phospholane

) For open-chain pentaalkoxyphosphoranes, see D. B. Denney and S. L. Gough, *J. Am. Chem. Soc.*, **87**, 138 (1965), and references therein.  
 9) F. Ramirez, O. P. Madan, and S. R. Heller, *ibid.*, **87**, 731 (1965).  
 10) The spectrum of VI had a strong band at 12.0  $\mu$ , which could be due to the hydrogen out-of-plane deformations of the vinyl group; see J. Bellamy, "The Infrared Spectra of Complex Molecules," John Wiley and Sons, Inc., New York, N. Y., 1958, p. 51.

VI. A similar alkylation by the phospholene IV was previously reported<sup>12</sup> and is shown in formulas XII  $\rightarrow$  XIII.

**Reaction of the Phospholane VI with Bromine.** This reaction was carried out in  $CCl_4$  solution at 0° and gave  $\alpha$ -bromo- $\alpha$ -hydroxy- $\beta$ -diketone XV in quantitative yield.

A possible mechanism is shown in formula XIV. It should be noted that the bromination of the phospholene IV gave  $\alpha$ -bromo- $\alpha$ -ketol phosphate<sup>12</sup> XVII, probably by a similar path.

**Hydrolysis of the  $\alpha$ -Hydroxy- $\beta$ -diketone Phosphotriester XI.** The phosphotriester XI was converted into 3-methylpentan-3-ol-2,4-dione or diacetylmethylcarbinol<sup>13,14</sup> (XVIII) by aqueous benzene at 80°.

(12) F. Ramirez and N. B. Desai, *J. Am. Chem. Soc.*, **82**, 2652 (1960).  
 (13) "Water solutions" of diacetylmethylcarbinol have been described (cf. ref 14). The pure alcohol was not isolated, and, consequently, analytical data were not provided. The bis(2,4-dinitrophenylhydrazones) was said to melt at 234–238°. The water solutions of the alcohol were made by acid hydrolysis of its acetate, which was prepared from  $\alpha$ -methyl- $\alpha$ -acetylacetone and lead tetraacetate.  
 (14) (a) E. Juni and G. Heym, *Arch. Biochem. Biophys.*, **67**, 410 (1957); (b) E. Juni and G. Heym, *J. Biol. Chem.*, **218**, 365 (1956).

This is a remarkably facile hydrolysis; trimethyl phosphate, or even dimethylphosphoacetoin (XIII), was not affected by water in boiling benzene, under comparable conditions. We have shown<sup>18</sup> that the second-order rate constant for the hydroxide ion catalyzed conversion of dimethylphosphoacetoin (XIII) into acetoin and dimethyl hydrogen phosphate was  $k_2 = 360 \text{ l. mole}^{-1} \text{ sec}^{-1}$ , at 25°, in water at pH 7.7–8.3. This was at least  $2 \times 10^6$  times faster than the corresponding value for trimethyl phosphate. Two possible explanations were proposed for this rate difference. (1) The acceleration could be due to the unsaturated nature of the leaving group and to hydrogen-bonding assistance (formula XIX). (2) The effect might result from carbonyl participation and oxyphosphorane formation during the hydrolysis (formula XX). Subsequently, a third explanation involving a hydroxyepoxide intermediate was proposed<sup>16</sup> (formula XXI).

Rate data for the hydroxide ion catalyzed hydrolysis of the hydroxydiketone phosphate XI are not available yet. However, it seems at least possible, that the extraordinarily rapid hydrolysis in aqueous benzene might involve the oxyphosphorane intermediate XXII.

**Hydrolysis of the Phospholane VI.** The phospholane VI was readily converted into diacetylmethylcarbinol (XVIII) by an excess of water in benzene solution at 80°.

When 1 molar equiv of water, or of D<sub>2</sub>O, was added to a solution of the phospholane VI in benzene, or in deuteriochloroform, four substances were produced almost instantaneously at 20°, or even at 0°. These were trimethyl phosphate, the hydroxydiketone XVIII, the dimethyl phosphate ester XI derived from this alcohol, and methanol. There was no evidence for the formation of the cyclic phosphotriester XXV. These conclusions were reached by an examination of the P<sup>31</sup> and the H<sup>1</sup> nmr data of the solutions at various times. These results are explained in terms of the intermediates XXIII and XXIV.

Support for the formation of intermediates like XXIII and XXIV has been adduced previously.<sup>17–19</sup>

(16) (a) H. Witzel, A. Botta, and K. Dimroth, *Ber.*, **98**, 1465 (1965); (b) T. C. Bruice and S. J. Benkovic, "Biorganic Mechanisms," Vol. 2, W. A. Benjamin, Inc., New York, N. Y., 1966, p 104, have recently discussed this problem.

(17) F. Ramirez, O. P. Madan, and C. P. Smith, *J. Am. Chem. Soc.*, **87**, 670 (1965).

In particular, it should be noted that the hydrolysis of the phospholene IV gave trimethyl phosphate, acetoin, dimethylphosphoacetoin (XIII), *acetoinenediol cyclophosphate* (XXVI), and methanol. The relative proportion of these products could be greatly altered by changes in temperature and other experimental conditions.<sup>17</sup>

## Discussion

The condensation of  $\alpha$ -dicarbonyl compounds with ketenes by means of trialkyl phosphites opens a new route to a variety of polyoxygenated functions related to the carbohydrates. The phosphate esters of these sugary-like materials can also be obtained in this manner (eq 1).

The various steps in these transformations can be carried out rapidly and under exceptionally mild conditions. The final products can be isolated easily and in high yields. Experiments are now under way to delimit the scope of these reactions in terms of (1) variations in the structure of the carbonyl compounds and the ketenes; (2) further transformations of the

(18) (a) F. Ramirez, N. B. Desai, and N. Ramanathan, *ibid.*, **85**, 1874 (1963); (b) F. Ramirez, O. P. Madan, N. B. Desai, S. Meyerson, and E. M. Banas, *ibid.*, **85**, 2681 (1963).

(19) The formation of an intermediate (rather than a transition state) with quintuply connected phosphorus, which we have advocated to explain our observations on the hydrolysis of pentaerythritol phosphates and of five-membered cyclic phosphotriesters (see ref 17 and 18), has been recently proposed also by Westheimer and co-workers to account for their observations during a comprehensive study of the hydrolysis of cyclic phosphates, phosphonates, and phosphinates; see E. A. Dennis and F. H. Westheimer, *ibid.*, **88**, 3431, 3432 (1966), and previous references given there.

carbonylketene phosphite adducts to polyfunctional phosphorus-free materials; (3) synthesis of new types of polyfunctional phosphate esters and further transformations of them.

It should be noted that the combination of the oxyphosphorane condensation with a hydrolytic step accomplishes the following objective<sup>20</sup>

Formally, the reductive phosphorylation of the  $\alpha$ -dicarbonyl compound by a phosphite ester in the presence of ketene amounts to a condensation between biacetyl and acetaldehyde, or its equivalent, acetoin and ketene.

Diacetylmethylcarbinol (XVIII) and acetoin were reported to be formed simultaneously when biacetyl was used as the substrate for the enzyme pyruvic oxidase.<sup>14,21</sup>

## Experimental Section

The analyses were performed by the Schwarzkopf Microanalytical Laboratory, Woodside, N. Y. The instrumentation was described previously.<sup>4</sup> All  $P^{31}$  nmr shifts are given in parts per million from 85%  $\text{H}_3\text{PO}_4$  as zero; they were determined at 40.5 Mc/sec. All  $H^1$  nmr shifts are given in parts per million from TMS as 10 ( $\tau$  values); they were determined at 60 or at 100 Mc/sec, as indicated.

**Reaction of Ketene with 2,2,2-Trimethoxy-4,5-dimethyl-1,3,2-dioxaphospholene (IV).** Ketene was bubbled through a stirred solution of the phospholene IV (95 g) in methylene chloride (75 ml) kept in an ice bath.  $H^1$  nmr analysis showed the complete disappearance of IV within 1.5 hr. The solvent and some of the acetone introduced with the ketene were removed at 20°, first at 20 mm, then at 1 mm. The residue was distilled through a 6-in. Vigreux column. Fraction 1 (19 g) was collected below 55° (0.3 mm) and consisted of the adduct VI contaminated with some trimethyl phosphate. Fraction 2 (85 g) was 2,2,2-trimethoxy-4-methylene-5-acetyl-5-methyl-1,3,2-dioxaphospholane (VI), bp 56–57° (0.1 mm). The spectral characteristics of this material did not change after redistillation. A sample fractionated through a 24-in. spinning-

band column had bp 62° (0.2 mm); prolonged heating may lead to partial decomposition.

*Anal.* Calcd for  $\text{C}_8\text{H}_{17}\text{O}_6\text{P}$ : C, 42.9; H, 6.7; P, 12.3; mol wt, 252. Found: C, 42.5; H, 6.8; P, 12.1; mol wt, 247.

The  $P^{31}$  nmr spectrum (neat liquid) had a multiplet at +51.4 ppm vs.  $\text{H}_3\text{PO}_4$ . The  $H^1$  nmr spectrum in  $\text{CDCl}_3$  had a 1  $H^1$  doublet of doublets at  $\tau$  5.80,  $J_{\text{HH}} = 1.9$  cps,  $J_{\text{HP}} = 1.9$  cps, and a second 1  $H^1$  doublet of doublets at  $\tau$  6.21,  $J_{\text{HH}} = 1.9$  cps,  $J_{\text{HP}} = 1.4$  cps; the separation between the centers of these two multiplets was 23 cps at 60 Mc/sec and 39 cps at 100 Mc/sec. The spectrum had also a 9  $H^1$  doublet at  $\tau$  6.40,  $J_{\text{HP}} = 13$  cps, and 3  $H^1$  singlets at  $\tau$  7.82 and 8.50, respectively. Better resolution was achieved in benzene, where the signals were at  $\tau$  5.80, 6.20, 6.45, 7.88, and 8.52, respectively. The low-field vinyl phosphorane protons had the appearance of a distorted triplet in all solvents.

The infrared spectrum ( $\text{CH}_2\text{Cl}_2$ ) had bands ( $\mu$ ) at 3.43 (w), 3.55 (w), 5.80 (s) ( $\text{C}=\text{O}$ ), 6.00 (m) ( $\text{C}=\text{CO}$ ), 6.90 (w), 7.30 (w), 7.40 (w), 7.75 (m), 8.50 (m), 8.60 (m), 9.20 (vs) ( $\text{POCH}_3$ ), 10.00 (vs), 10.45 (w), 11.42 (m), 12.00 (s) (probably H out-of-plane deformation of  $\text{OC}=\text{CH}_2$ , with shoulder at 11.85), and 12.90 (ms).

Redistillation of fraction 1 using a 12-in. spinning-band column gave an additional amount of adduct VI, which was formed in about 90% yield. The  $H^1$  nmr of the original distillation residue showed the presence in it of more adduct VI.

**Reaction of the Phospholane VI with Hydrogen Chloride.** Anhydrous hydrogen chloride was passed through a solution of the dioxaphospholane VI (19 g) in methylene chloride (50 ml) at 0° until saturation was achieved. The solvent was removed at 20° (20 mm); the  $H^1$  nmr spectrum of the crude residue showed the presence of nearly pure diketo phosphate XI. Short-path distillation gave pure 3-methylpentan-3-ol-2,4-dione dimethyl phosphate (XI), bp 87° (0.1 mm), yield 17 g (90%),  $n_D^{20}$  1.4358;  $\delta P^{31}$  (in  $\text{CDCl}_3$ ) = +2.9 ppm, a septet.

*Anal.* Calcd for  $\text{C}_8\text{H}_{15}\text{O}_6\text{P}$ : C, 40.3; H, 6.30; P, 13.0. Found: C, 40.8; H, 6.5; P, 12.6.

The  $H^1$  nmr spectrum in  $\text{CDCl}_3$  had a 6  $H^1$  doublet at  $\tau$  6.18,  $J_{\text{HP}} = 11$  cps ( $\text{CH}_2\text{O}$ ), a 6  $H^1$  singlet at  $\tau$  7.75 (acetyl), and a 3  $H^1$  singlet at  $\tau$  8.25 (methyl). No major differences were observed in benzene solution. The infrared spectrum ( $\text{CH}_2\text{Cl}_2$ ) had bands at 3.45 (w), 5.80 (s), 5.85 (s) ( $2\text{C}=\text{O}$ ), 6.95 (w), 7.42 (m), 7.85 (s), (PO), 8.45 (w), 9.58 (vs) ( $\text{POCH}_3$ ), 9.85 (s), 11.70 (s)  $\mu$ .

**Reaction of the Phospholane VI with Bromine.** A solution of bromine (11.4 g, 71 mmol) in  $\text{CCl}_4$  (25 ml) was added over a period of 1 hr to a stirred solution of the phospholane VI (18 g, 71 mmol) in  $\text{CCl}_4$  (50 ml) at 0°. The colorless solution was evaporated at 20° (20 mm). The residue gave only one  $P^{31}$  nmr signal at  $\pm 2.6$  ppm (in  $\text{CH}_2\text{Cl}_2$ ); the  $H^1$  nmr spectrum was very similar to that of the distilled bromoketo phosphate XV. The analytical sample of 1-bromo-3-methylpentan-3-ol-2,4-dione dimethyl phosphate (XV) was obtained as a pale yellow oil,  $n_D^{20}$  1.4697, after short-path distillation; the approximate boiling point was 106–108°. XV was obtained in nearly quantitative yield. The material slowly turns pink and then reddish brown on prolonged standing at 20°,  $\delta P^{31}$  ( $\text{CDCl}_3$ ) = +2.9 ppm, septet.

*Anal.* Calcd for  $\text{C}_8\text{H}_{14}\text{O}_6\text{BrP}$ : C, 30.3; H, 4.4; Br, 25.3; P, 9.7. Found: C, 29.9; H, 4.5; Br, 24.6; P, 9.3.

The  $H^1$  nmr spectrum in  $\text{CDCl}_3$  had a 2  $H^1$  singlet at  $\tau$  5.58 ( $\text{CH}_2\text{Br}$ ); a 3  $H^1$  doublet at  $\tau$  6.16,  $J_{\text{HP}} = 11.5$  cps ( $\text{CH}_2\text{OP}$ ), and a second 3  $H^1$  doublet with about the same coupling constant displaced 0.6 cps to higher field ( $\text{CH}_2\text{OP}$ ); a 3  $H^1$  singlet at  $\tau$  7.67 (acetyl); and a 3  $H^1$  singlet at  $\tau$  8.15 (methyl). The infrared spectrum ( $\text{CH}_2\text{Cl}_2$ ) had bands at 5.70 (s), 5.80 (s) ( $2\text{C}=\text{O}$ ), 6.90 (m), 7.30 (m), 7.40 (m), 7.80 (s) (PO), 8.40 (m), 8.80 (m), 9.4–9.6 (vs) ( $\text{POCH}_3$ ), and 11.65 (s).

**Hydrolysis of 3-Methylpentan-3-ol-2,4-dione Dimethyl Phosphate (XI).** Water (20 ml, 15 molar equiv) was added to a solution of the phosphate ester XI (19 g) in benzene (70 ml). The mixture was kept 6 hr at reflux. The water layer was separated and extracted with two 40-ml portions of benzene. The benzene extracts and the original benzene layer were combined, dried over  $\text{MgSO}_4$ , and distilled through a 6-in. Vigreux column to remove benzene (care should be exercised to avoid loss of product XVIII). The spectral analysis of the crude oil showed only one component, the hydroxydiketone XVIII. The analytical sample of 3-methylpentan-3-ol-2,4-dione or diacetylmethylcarbinol<sup>12</sup> (XVIII) had bp 43° (4.5 mm),  $n_D^{20}$  1.4272. XVIII was obtained in 67% yield.

*Anal.* Calcd for  $\text{C}_8\text{H}_{16}\text{O}_5$ : C, 55.3; H, 7.8. Found: C, 55.7; H, 7.9.

The  $H^1$  nmr spectrum in  $\text{CDCl}_3$  had a 1  $H^1$  singlet at  $\tau$  5.14 (OH), a 6  $H^1$  singlet at  $\tau$  7.76 (acetyl), and a 3  $H^1$  singlet at  $\tau$  8.48 (methyl).

(20) (a) F. Ramirez and S. Dershowitz, *J. Org. Chem.*, **23**, 778 (1958);  
(b) F. Ramirez and S. Dershowitz, *J. Am. Chem. Soc.*, **81**, 587 (1959);  
(c) F. Ramirez, E. H. Chen, and S. Dershowitz, *ibid.*, **81**, 4338 (1959).  
(21) R. P. Hullin and H. Hassall, *Biochem. J.*, **83**, 298 (1962).

The infrared spectrum in  $\text{CH}_2\text{Cl}_2$  had bands at ( $\mu$ ) 2.92 (OH), 5.85 (CO), 7.40, 8.35, and 8.70.

**Reaction of the Phospholane VI with an Excess of Water.** Water (8 ml, 462 mmoles) was added to a solution of the phospholane VI (15 g, 58 mmoles) in benzene (50 ml). The mixture was kept 4 hr at reflux. The water layer was extracted with benzene. The combined benzene extracts and original solution were fractionated as before. Diacetylmethylcarbinol (XVIII) was isolated in 75% yield.

**Reaction of the Phospholane VI with 1 Molar Equiv of Water.**  
**a. In  $\text{CDCl}_3$  Solution.** Water (1 molar equiv) was added to a solution of the phospholane VI in  $\text{CDCl}_3$  at  $20^\circ$ . After the vigorous exothermic reaction had subsided, the solution was analyzed by  $\text{P}^{31}$  nmr spectroscopy at 40.5 Mc/sec. Only the signals due to trimethyl

phosphate and to diacetylmethylcarbinol dimethyl phosphate (XI) were observed. The experiment was repeated using  $\text{D}_2\text{O}$  and a 6 M solution of the phospholane VI in  $\text{CDCl}_3$ ; the  $\text{H}^1$  nmr after 5 min had the signals due to trimethyl phosphate, the deuteriodiacetylmethylcarbinol (XVIII), the open phosphotriester XI, and deuteriomethanol.

**b. In Benzene Solutions.** Water (1 molar equiv) was added to a 2 M solution of phospholane VI in benzene at  $0^\circ$ . The solvent was removed after ca. 1 min at  $0^\circ$  (3 min). The residue was dissolved in  $\text{CDCl}_3$ . The  $\text{P}^{31}$  and  $\text{H}^1$  nmr spectra showed the signals of the species mentioned above plus those of some unreacted phospholane VI. There was no evidence for the formation of the cyclic phosphate ester XXV.

## A New Synthesis of 5-Acylhydantoins, Precursors of $\beta$ -Keto- $\alpha$ -amino Acids

Fausto Ramirez,<sup>1</sup> S. B. Bhatia, and C. P. Smith

Contribution from the Department of Chemistry of the State University of New York at Stony Brook, Stony Brook, New York 11790.

Received February 21, 1967

**Abstract:** A new reaction leading to 5-acylhydantoins, the precursors of  $\beta$ -keto- $\alpha$ -amino acids, is described. In this reaction, a trialkyl phosphite induces the condensation of one molecule of an  $\alpha$ -diketone with two molecules of an aryl isocyanate with formation of the 5-acylhydantoin and a trialkyl phosphate. Three steps are involved, and the intermediates can, but need not, be isolated. The intermediates are organic compounds with pentavalent phosphorus as shown by  $\text{P}^{31}$  nmr spectroscopy.

The hydantoins I are one of the classical synthetic precursors of the  $\alpha$ -amino acids<sup>2</sup> II.

This type of heterocycle is associated with powerful anticonvulsant action; for example, 5,5-diphenylhydantoin (Dilantin) is widely used in the control of epilepsy.<sup>2</sup> Consequently, many alkyl- and arylhydantoins have been prepared.<sup>2</sup> On the other hand, the 5-acylhydantoins, which are the precursors of  $\beta$ -keto- $\alpha$ -amino acids, have not received much attention.<sup>2c</sup> Modifications of the carbonyl function of the 5-acetylhydantoins prior to hydrolysis would make available a variety of  $\beta$ -substituted  $\alpha$ -amino acids.

This paper describes a new approach to 5-acylhydantoins VI based on the condensation of an  $\alpha$ -dicarbonyl compound III with an isocyanate<sup>3</sup> IV under the influence of a trialkyl phosphite<sup>4,5</sup> V.

### Results

The 2,2,2-trialkoxy-1,3,2-dioxaphospholene<sup>6</sup> (VIII), prepared from biacetyl and trimethyl phosphite, reacted with phenyl isocyanate (IX) at  $30^\circ$ . The course of the reaction was followed by means of infrared and  $\text{H}^1$  and  $\text{P}^{31}$  nmr spectroscopy. Two distinct steps were observed. The first step was the nucleophilic addition of a carbon atom of the phospholene VIII to the carbonyl carbon of the isocyanate. The product was 2,2,2-trimethoxy-4-phenylimino-5-acetyl-5-methyl-1,3,2-dioxaphospholane (X).

(6) The literature has been reviewed by F. Ramirez, *Pure Appl. Chem.*, **9**, 337 (1964).

The phospholane X may arise in one concerted step which requires little or no charge separation.<sup>7</sup> There was no experimental indication of the presence of open dipolar structures<sup>8</sup> such as XI and XII.

Furthermore, a structural isomer of the pentaoxyphosphorane X, namely, the aminotetraoxyphosphorane XIII, could not be detected. This is consistent with our previous observations on the relative stabilities of these ring systems.<sup>8,9</sup>

The phospholane X reacted with a second molecule of phenyl isocyanate. The products were trimethyl phosphate (VII) and 1,3-diphenyl-5-acetyl-5-methylhydantoin (XV).

No intermediate could be detected in this reaction, but we assume that the nitrogen of the phospholane X first performed a nucleophilic addition to the carbon of the isocyanate to form a dipolar intermediate XIV.

(7) (a) F. Ramirez, A. V. Patwardhan, and C. P. Smith, *J. Org. Chem.*, **30**, 2575 (1965); (b) *ibid.*, **31**, 474 (1966); (c) *ibid.*, **31**, 3159 (1966).

(9) F. Ramirez, *Bull. Soc. Chim. France*, 2443 (1966).

The latter then cyclized to a five-membered hydantoin ring with ejection of phosphate ester, instead of forming a seven-membered cyclic phosphorane.

A structural isomer of the hydantoin, which would be derived from an attack by oxygen on carbon in the intermediate XIV, could not be isolated.

It was shown that the isocyanate dimer XVI, prepared by addition of traces of tri-*n*-butylphosphine to the isocyanate,<sup>10</sup> did not react with the phospholene VIII.

The rates of the reactions of phenyl isocyanate with the phospholene VIII and with the phospholane X were very similar. Therefore, the best procedure to make phospholane X involved a slow addition of isocyanate to an excess of phospholene VIII.

The preparation of hydantoin XV was very simple. Isocyanate (2 moles) and phospholene VIII (1 mole) were allowed to react in boiling methylene chloride solution. Compound XV was isolated in 75% yield. Small amounts of a second substance, not investigated further, were found in the residues.

It was possible to condense biacetyl with 2 moles of phenyl isocyanate and 1 mole of trimethyl phosphite *in situ*, without isolation of intermediates, as shown in the scheme III + IV + V → VI + VII.

The following data established the structure of the phospholane X. (1) The  $P^{31}$  nmr shift,  $\delta P^{31} = +57.8$  ppm *vs.*  $H_3PO_4$ , showed that five oxygen atoms were bound to the phosphorus.<sup>6,9,11</sup> The shift of the aminotetraoxyphosphorane XIII should fall in the range 30–40 ppm.<sup>8</sup>

(2) The  $H^1$  nmr spectrum of X had a 3  $H^1$  singlet at  $\tau$  7.71 and another at  $\tau$  8.36, which correspond to the acetyl and the methyl groups, respectively.<sup>6,9</sup> The 9  $H^1$  of the three methoxy groups gave rise to one doublet,  $J_{HP} = 13$  cps, at  $\tau$  6.41. As was the case with a number of related compounds, the three methoxy groups were magnetically indistinguishable at 20°, probably due to rapid positional exchange in the trigonal bipyramid.<sup>6,9</sup>

(3) The infrared spectrum of X had strong bands at 5.98 and 5.78  $\mu$ , which are attributed to the  $C=N$  and the  $C=O$  groups, respectively.

The hydantoin XV had infrared bands at 5.62 and 5.83  $\mu$  attributed to the carbonyl groups at the 4 and 2 positions, respectively.<sup>12</sup> The band due to the acetyl carbonyl was at 5.78  $\mu$ . The  $H^1$  nmr spectrum of XV had the expected 10  $H^1$  aromatic multiplet and the 3  $H^1$  singlets at  $\tau$  7.68 and 8.28 due to the acetyl and the methyl groups, respectively.

*p*-Cyanophenyl isocyanate (XVII) reacted faster than the unsubstituted isocyanate IX with the phospholene VIII. The N-(*p*-cyanophenyl)hydantoin (XVIII) was isolated in 75% yield.

## Discussion

The formation of a 2,2,2-trialkoxo-1,3,2-dioxaphospholane (XX) from the reaction of the  $\alpha$ -dicarbonyl compound XIX with the trialkyl phosphite V was first reported in 1961.<sup>13</sup> The exact nature of the precursor, XXI or XXII, of the phospholane XX could not be established, since this precursor reacted very rapidly with a second molecule of the carbonyl compound.

Shortly thereafter, it was demonstrated that isolable 2,2,2-trialkoxo-1,3,2-dioxaphospholenes (XXIII) underwent nucleophilic additions to carbonyl functions XXIV with formation of analogous phospholanes<sup>14</sup> XXV.

(13) F. Ramirez and N. Ramanathan, *J. Org. Chem.*, **26**, 3041 (1961).

(14) F. Ramirez, N. Ramanathan, and N. B. Desai, *J. Am. Chem. Soc.*, **84**, 1317 (1962).

Subsequently, the mechanism and the synthetic scope of this new reaction were investigated in detail.<sup>6,7,9</sup>

More recently, it was found that the phospholene VIII condensed very readily with ketene XXVI to give 4-methylene-2,2,2-trialkoxo-1,3,2-dioxaphospholane<sup>11</sup> (XXVII).

The *exo*-methylene phospholane XXVII proved to be a valuable reaction intermediate. It was readily converted into the phosphate esters of  $\alpha$ -hydroxy- $\beta$ -diketones and of  $\gamma$ -bromo- $\alpha$ -hydroxy- $\beta$ -diketones<sup>11</sup> XXVIII and XXIX.

The present paper emphasizes the generality of this new method of making carbon-carbon single bonds by means of triply and quintuply connected phosphorus compounds.<sup>16</sup> Evidently, the method seems adaptable to the syntheses of  $\alpha$ -amino acids and of carbohydrates. These studies are now in progress.

## Experimental Section

The analyses were performed by the Schwarzkopf Microanalytical Laboratory, Woodside, N. Y. The instrumentation was described previously.<sup>6,7</sup> All P<sup>31</sup> nmr shifts are given in parts per million from 85% H<sub>3</sub>PO<sub>4</sub> as zero; they were measured at 40.5 Mc/sec.

**Reaction of 2,2,2-Trimethoxy-4,5-dimethyl-1,3,2-dioxaphospholene (VIII) with 1 Molar Equiv of Phenyl Isocyanate.** The phospholene<sup>6,7</sup> VIII (11.8 g, 56 mmoles) and the isocyanate IX (5.9 g, 50 mmoles) were mixed at 20° in the absence of solvent and with protection against moisture. There was no visible reaction, but the infrared and H<sup>1</sup> nmr spectra showed evidence of reaction within 1 hr. After 20 hr at 20° under stirring, all the isocyanate had been consumed and there were new infrared bands at 5.62, 5.78, 5.82, and 5.93  $\mu$ . The H<sup>1</sup> nmr spectrum in CDCl<sub>3</sub> showed some unreacted dioxaphospholene VIII, some trimethyl phosphate (doublet at  $\tau$  6.32,  $J_{\text{PH}} = 11$  cps), the dioxaphospholane X, and the hydantoin XV. Better resolution was achieved in CH<sub>2</sub>Cl<sub>2</sub>. The P<sup>31</sup> nmr spectrum in CH<sub>2</sub>Cl<sub>2</sub> confirmed the presence of the phospholene ( $\delta\text{P}^{31} = +48.9$  ppm), the phospholane ( $\delta\text{P}^{31} = +57.8$  ppm), and trimethyl phosphate ( $\delta\text{P}^{31} = -2.2$  ppm).

(15) F. Ramirez, S. B. Bhatia, and C. P. Smith, *ibid.*, **89**, 3026 (1967).

(16) While this work was in progress, A. J. Kirby [*Tetrahedron*, **22**, 3001 (1966)] described the reaction of the dioxaphospholene VIII with carbon disulfide. Our studies of the reaction of VIII with a number of systems having cumulated double bonds will be published soon.

mixture was freed from the phospholene VIII and trimethyl phosphate by short-path distillation at 0.3 mm. The residue dissolved in ether (40 ml) and kept at  $-20^{\circ}$  to effect crystallization of the hydantoin XV. The latter (2.0 g, 28% yield) was collected and was recrystallized from benzene-hexane. 1,3-Diphenyl-5-methylhydantoin (XV) had mp  $134-135^{\circ}$ .

*Anal.* Calcd for  $C_{18}H_{16}O_2N_2$ : C, 70.1; H, 5.2; N, 9.1; mol wt, 300 (cryo). Found: C, 70.2; H, 5.3; N, 9.3; mol wt, 300 (cryo in benzene).

$^1H$  nmr spectrum ( $\tau$  values in parts per million from TMS in  $CDCl_3$ ) had signals at 2.58 (four aromatic protons), 2.71 (three aromatic protons), 7.68 (three acetyl protons), and 8.28 (three methyl protons). The infrared spectrum (in  $CH_2Cl_2$ ) had bands at 2.8 (m), 5.78 (s), 5.82 (s), 6.23 (w), 6.67 (m), 7.13 (ms), 7.42 (m), 7.45 (m)  $\mu$ .

The ether filtrate was evaporated. The residue was shown to contain more hydantoin and small amounts of trimethyl phosphate; a main component was the dioxaphospholane X. The latter is prepared as described below.

**Reaction of the Dioxaphospholene VIII with 2 Molar Equiv of Phenyl Isocyanate.** Optimum Conditions for the Synthesis of Hydantoin XV. The phospholene VIII (9.8 g, 46.7 mmoles) and phenyl isocyanate (11.1 g, 93.5 mmoles) were dissolved in 25 ml of methylene chloride. The solution was kept 24 hr at reflux temperature, and then the solvent was removed at  $20^{\circ}$  (20 mm). The residue was kept several hours at  $-20^{\circ}$  under ether, and the first crop (8 g) of nearly pure hydantoin XV was filtered. The ether was evaporated to remove first ether and then trimethyl phosphate (0.1 mm, bath at  $80^{\circ}$ ). The residue was kept several hours at  $20^{\circ}$  under ethanol giving a second crop (2.1 g) of hydantoin XV; combined yield 70%. The material balance consisted of more hydantoin (estimated 10–15%) and a second substance whose structure was not investigated further.

**Direct Synthesis of 5-Acyl-5-alkylhydantoin (XV) from  $\alpha$ -Diketone, Isocyanate, and Phosphite without Isolation of Intermediates.** 1,3-Diphenyl (8.6 g, 100 mmoles) and phenyl isocyanate (24 g, 200 mmoles) were dissolved in 20 ml of methylene chloride. The solution was cooled to  $0^{\circ}$  and was treated with trimethyl phosphite (100 mmoles). The solution was stirred 1 hr at  $0^{\circ}$  and 0.5 hr at  $20^{\circ}$ . It was then kept at reflux for 7 hr; the infrared spectrum showed little unreacted isocyanate. The reaction mixture was worked up as described above, after an additional 8–10-hr reflux at  $20^{\circ}$ . The hydantoin was isolated in 70% yield.

**Isolation of 2,2,2-Trimethoxy-4-phenylimino-5-acetyl-5-methyl-dioxaphospholane (X).** Phenyl isocyanate (9.7 g, 82 mmoles) was introduced into the stirred dioxaphospholene VIII (34.3 g, 82 mmoles) over a 12-hr period, at  $20^{\circ}$ . The mixture was stirred for an additional 12-hr period. The excess of phospholene and a small amount of trimethyl phosphate were removed at 0.1 mm and a temperature of  $80^{\circ}$ . The residue (22 g) was the viscous, non-crystalline dioxaphospholane X. The latter had the following spectral characteristics:  $\delta P^{31} = +57.8$  ppm ( $CH_2Cl_2$ );  $\tau$  ( $CDCl_3$ ) (doublet),  $J_{HP} = 13$  cps, 7.72 (singlet), 8.35 (singlet);  $\tau$  ( $CH_2Cl_2$ ) 6.50,  $J_{HP} = 13$  cps, 7.75 and 8.40;  $\tau$  (benzene) 6.60,  $J_{HP} = 13$  cps, 7.80 and 8.40; infrared bands ( $CH_2Cl_2$ ) at 5.78 (s), 5.82 (s), 6.27 (m), 6.70 (ms), 6.92 (m), 7.20 (ms), 7.40 (m), 8.50 (m),

8.70 (m), 9.30–9.40 (vs and broad), 9.86 (m), 11.72 (ms), and 12.15 (ms)  $\mu$ .

**Reaction of the Trimethyl Bisacetyl(phenyl isocyanate)phosphite Adduct X with Phenyl Isocyanate.** The phospholane X obtained above was converted into the hydantoin XV by 1 molar equiv of phenyl isocyanate in methylene chloride at reflux temperature.

**Effect of Temperature and of Solvent on the Yield of Hydantoin XV.** (a) In 1,2-Dichloroethane. The phospholene VIII and 2 molar equiv of phenyl isocyanate were dissolved in 1,2-dichloroethane, and the solution was kept at various temperatures for various periods of time. The hydantoin XV was isolated in the following yields: 65% after 10 hr at  $55^{\circ}$ , 59% after 8 hr at  $65^{\circ}$ , 63% after 17 hr at  $65^{\circ}$ . A second substance was also isolated from these experiments in about 10% yield.

(b) In Ether. Significant amounts of phenyl isocyanate remained after 24 hr at reflux temperature.

(c) In the Absence of Solvent. The hydantoin XV was isolated in ca. 40% yield after 24 hr at  $20^{\circ}$ . At higher temperatures the reaction was erratic and, at times, violent. In one case, 48% of hydantoin was isolated after 4 hr at  $60^{\circ}$ .

**Reaction of 5-Acylhydantoin XV with 2,4-Dinitrophenylhydrazine.** The hydantoin XV (800 mg) in ethanol (30 ml) was treated with a solution made from 2,4-dinitrophenylhydrazine (1.2 g),  $H_2SO_4$  (1.5 ml, concentrated), and methanol (30 ml). The red solution was kept 2 hr at reflux, cooled, and filtered yielding the yellow 2,4-dinitrophenylhydrazone, mp  $195-196^{\circ}$  (benzene).

*Anal.* Calcd for  $C_{24}H_{20}O_6N_4$ : N, 17.2. Found: N, 17.1.

The infrared spectrum ( $CH_2Cl_2$ ) had bands at 3.15 (w), 5.62 (m), 5.80 (s), 6.18 (s), 6.27 (s), 6.67 (s), 7.15 (s), 7.46 (s), and 7.62 (m)  $\mu$ , among others.

**Reaction of the Dioxaphospholene VIII with 2 Molar Equiv of *p*-Cyanophenyl Isocyanate (XVII).** The phospholene VIII (9.1 g, 43.1 mmoles) was added to a suspension of *p*-cyanophenyl isocyanate (12.5 g, 86.4 mmoles) in 1,2-dichloroethane at  $20^{\circ}$ . The mixture was stirred at  $20^{\circ}$  for 12 hr. The first crop of the cyanohydantoin XVIII (8.8 g) was filtered. The filtrate was evaporated, and the residue was kept several hours at  $20^{\circ}$  under ether to give a second crop of hydantoin (1.1 g), combined yield 70%. The analytical sample of 1,3-di-(*p*-cyanophenyl)-5-acetyl-5-methylhydantoin (XVIII) had mp  $234-235^{\circ}$  (from  $CH_2Cl_2 \cdot CH_2Cl_2$ ).

*Anal.* Calcd for  $C_{28}H_{18}O_2N_4$ : C, 67.1; H, 3.9; N, 15.6. Found: C, 67.2; H, 4.1; N, 15.7.

The  $^1H$  nmr in  $AsCl_3$  had the following signals (in  $\tau$ ): aromatic multiplet at 2.1–2.6, acetyl protons at 7.53, and methyl protons at 8.09. The infrared spectrum (in  $CH_2Cl_2$ ) had bands at 4.50 (m) (CN), 5.62 (ms) (CO), 5.78 (s) (CO), 5.82 (s) (CO), 6.23 (ms), 6.65 (ms), 7.20 (s), and 7.48 (ms)  $\mu$ .

**Attempted Reaction of the Dioxaphospholene VIII with the Phenyl Isocyanate Dimer<sup>10</sup> XIV.** The phenyl isocyanate dimer XIV was formed immediately when a few drops of tri-*n*-butylphosphine was added to the isocyanate.<sup>10</sup> The dimer was filtered, washed with ethanol, and recrystallized from boiling toluene; it had mp  $174-175^{\circ}$  and showed infrared bands at 5.60 (s), 6.23 (w), 6.67 (s), and 7.23 (s)  $\mu$  in  $CH_2Cl_2$ , in which it was slightly soluble.

The dimer failed to react with the dioxaphospholene VIII, with or without solvents, at  $20^{\circ}$  for several days.

Pyracylenes. III.<sup>1</sup> Radical Anions in the Pyracylene System

Stephen F. Nelsen, Barry M. Trost, and Dennis H. Evans

Contribution from the Department of Chemistry, University of Wisconsin, Madison, Wisconsin 53706. Received November 25, 1966

**Abstract:** The pyraclosemiquinone anion was generated from the quinone under a variety of conditions and compared to the related semiquinones from acenaphthaquinone and 1,2-diketopyracene. The hyperfine splitting constants were found to be dependent upon the method of generation, one set of values obtained by chemical reduction in the presence of base and the other by electrochemical generation. The differences are attributed to the presence of the "free" ion under the base conditions and chelates or tight ion pairs under the electrochemical conditions. The correlation of these spectra with molecular orbital theory is discussed. Stone's theory of  $g$  factors is modified to allow one to calculate spin density at a heteroatom, oxygen, from two experimental quantities,  $g$  factors, and half-wave potentials. Thus, pyraclosemiquinone is found to have approximately one-fifth the spin density at oxygen compared to other semiquinones. This fact plus the large hyperfine splitting constants suggest that this semiquinone anion is more akin to hydrocarbon radical anions than normal semiquinone anions, in excellent agreement with theory. Protonation of the dianion of pyracycloquinone, generated electrochemically, under thermodynamic conditions occurred at carbon to produce diketopyracene. Strain energy and not resonance energy appears to be the determining factor in the equilibrium<sup>1</sup> between diketopyracene and dihydroxypyracylene.

The question of aromaticity is of fundamental theoretical and practical concern and has occupied the attention of many investigators. A particularly interesting compound having  $4n + 2$   $\pi$  electrons and fulfilling Craig's rules of aromaticity is pyracylene (I).<sup>2</sup> Calculations predict a resonance energy of  $5.42\beta$ ,<sup>3,4</sup> whereas the strain of bridging both *peri* positions with  $sp^2$  carbons is estimated to destabilize I by 48 kcal/mole.<sup>5</sup> The unique feature of the electronic structure of this molecule is the prediction that it will have an empty nonbonding molecular orbital, the simplest aromatic hydrocarbon predicted to have this electronic configuration. In order to investigate the properties of the pyracylene system, we synthesized the quinone II related to the parent hydrocarbon.<sup>1b,6</sup> Reduction of this quinone would produce a substituted pyracylene. Since no identifiable products could be isolated by standard reduction procedures,<sup>7</sup> we explored the one electron reduction product (II, pyraclosemiquinone) by the esr technique. This study and some comments

regarding correlations between esr spectra and MO calculations form the subject of this paper.

## Esr Spectra

To see if unusual electronic distribution attributable to the pyraclyl system in pyraclosemiquinone (II) is realized, the esr spectra of II, III, and IV were compared. Esr data for these semiquinones, prepared by reaction of the quinone with potassium *t*-butoxide in DMSO,<sup>8</sup> appears in Table I.

Table I. Esr Spectral Data (KO-*t*-Bu Reduction in DMSO)

Compd	$a_a$	$a_b$	$a_c$	$g$
II	$1.41 \pm 0.02$	2.45	2.12	2.0030 <sup>a</sup>
III	1.18	0.27	1.28	2.0044 <sup>b</sup>
IV	1.15	0.21	1.38	2.0043 <sup>b</sup>

<sup>a</sup> Error in  $g$  is estimated to be  $\pm 0.0002$ . <sup>b</sup> Error in  $g$  is estimated to be  $\pm 0.0001$ .

(7) B. M. Trost, to be published.

The splitting constants of acenaphthasemiquinone (III) are close to those reported<sup>9</sup> for the same species generated electrochemically. Placing a saturated two-carbon bridge across the *peri* positions of III to give IV slightly reduces the ring hydrogen splittings (and hence the ring spin density), which is expected. Because of the slightly electron-releasing character of alkyl compared to hydrogen, electronic density is shifted away from the alkyl group. Unsaturation of the *peri* two-carbon bridge (giving II) has a striking effect in that all of the proton splitting constants are raised, which shows that significantly more spin density is on the ring carbons in II than in III or IV. The largest change is at the  $b$  position, which has a tenfold increase in spin density, giving it the highest spin density, although the corresponding position of III and IV has the lowest. This is not predictable by simple resonance structure reasoning, for structures with spin at  $b$  cannot have the benefit of both benzene resonance and placing the

(8) G. R. Talaty and G. A. Russell, *J. Am. Chem. Soc.*, **87**, 4867 (1965).

(9) R. Dehl and G. K. Fraenkel, *J. Chem. Phys.*, **39**, 1793 (1963), give 1.17, 0.27, and 1.27  $g$ , respectively.

tive charge on oxygen, the most electronegative atom. The  $g$  value of II, 2.0030, is quite different from that of IV, and indeed from that of all other hydrocarbons, which have  $g$  factors which fall in a narrow range of 2.0040–2.0048. Both the splitting constants and  $g$  factor of pyraclosemiquinone (II) are to be quite unusual; these facts must be a result of unusual electronic distribution in this system.

For calculations of electronic distribution are for the perturbed, vapor phase species, it was desirable to generate II under a variety of experimental conditions to see if specific medium effects are important in determining the spin distribution. It was found that II could be formed with the weaker bases NaOH, KOH, and  $\text{Ba}(\text{OH})_2 \cdot 2\text{H}_2\text{O}$  if a DMSO solution of the quinone was agitated in the presence of the solid base, as even formed when a DMSO solution of pyraclosemiquinone was mixed with tetramethylammonium oxide. The need for base being present was demonstrated by carrying out the reduction at a mercury electrode using various supporting electrolytes (Figure 1). DMSO solutions 0.1  $M$  in tetraalkylammonium chlorides, sodium perchlorate, lithium chloride, and sodium bromide were all successful. Using DMF as solvent was 0.1  $M$  in tetrabutylammonium perchlorate, no difference in splitting constants for II from those observed in DMSO. The electrolytic reduction to give workable radical concentrations in DME and THF with alkali metal supporting electrolytes. Surprisingly, large amounts of II are not formed if a DME solution of pyraclosemiquinone is stirred with sodium metal (in contrast to the results in DMSO), but violet irradiation ( $\lambda$  366  $m\mu$ ) of such a mixture<sup>11</sup> leads to formation of II. Although sodium hydroxide is not visibly soluble in DME, the presence of base is necessary, for solutions in pure DME or 0.1  $M$  sodium perchlorate in DME fail to give radical upon irradiation.

Splitting constants observed under these conditions are summarized in Table II. For the alkali hy-

Irradiation of basic quinone solutions to give the semiquinones in situ process: E. C. Lucken, *J. Chem. Soc.*, 4234 (1964).

Figure 1. (A) The observed (top) and the calculated (bottom) spectrum of pyraclosemiquinone anion generated by treatment of the quinone with potassium  $t$ -butoxide in DMSO. (B) The observed (top) and the calculated (bottom) spectrum of pyraclosemiquinone anion generated by electrolysis in DMSO employing tetra- $n$ -butylammonium perchlorate as supporting electrolyte.

240  $m\mu$  for the potassium  $t$ -butoxide spectrum. Position assignments for the splitting constants which agree with MO predictions (*vide infra*) were proved by deuteration, the middle-sized splitting being changed as predicted [observed splitting constants 2.93 (2 H), 0.93 (2 H), and 0.44 (2 D)] when pyraclosemiquinone- $c,c$ - $d_2$  was electrolyzed.

There is a large "base effect" on the spectrum of II. Significantly higher spin density at the  $b$  and  $c$  positions of II is observed in the electrolytic spectra than in the  $t$ -butoxide spectrum. Since the "electrolytic" spectrum was observed with tetramethylammonium hydroxide, a stronger base than this is necessary to change the splittings. The irradiation spectrum is truly intermediate, the splitting constant observed being exactly (within experimental error) the average of the two extreme spectra. Changing cations does not affect the electrolytic spectrum much; there is a significant difference between tetraalkylammonium and alkali metal, but differences between alkali metals were not measurable.

Figure 2. Variation of  $h$  and  $k$  in Hückel calculations for pyracloquinone. The heavy line passes through  $h$  and  $k$  values for which  $E_A = E_B$ . To the right  $E_A < E_B$  (experiment shows this is fact), while to the left  $E_B < E_A$  ("crossed" region). Lines A and B give  $h$  and  $k$  values for best fit to the *t*-butoxide and electrolytic spectra, respectively. For the former, it was assumed the odd electron is in  $\psi_A$  in spite of the energy crossing.

We assign the differences in splitting constants observed to having "free" ions (II plus cation) and chelated ion pairs (V). We attribute the base effect to

preferential coordination of the alkoxide with the cation thus liberating the free radical anion II. Thus the electrolytic spectrum represents that of the chelate V. Metal splittings might be expected for V<sup>12</sup> in ether solvents; however, we have been unable to obtain high enough radical concentration for esr spectra by electrolytic reduction in ethers. In agreement with this interpretation is the observed spectrum when the radical was generated by irradiation of a solution of quinone in DME saturated with sodium hydroxide. Rapid equilibrium of chelate and free forms (lifetime less than  $ca. 10^{-7}$  sec) would lead to the averaged splitting constants observed. Since the hydroxide concentration is extremely low, the semiquinone anion is an effective competitor for chelation (or tight ion-pair formation).

When pyracloquinone is electrolytically reduced at potentials on the second polarographic wave (*vide infra*), II disappears and the dianion VI is presumably formed. If the applied potential is dropped to zero, a negative current is observed and II appears; the reduction is reversed.<sup>13</sup> In unpurified spectro grade DMF, however, III, not II, appears after high-potential

(12) Although the very stable tetracyanoethylene radical anion does not give metal splittings (M.C.R. Symons, Michigan State University, ESR Symposium, Aug 1-3, 1966) II is considerably stabler than other semiquinones, which do show metal splittings, even in the presence of base.<sup>10</sup>

(13) Breaking the circuit causes appearance of II at a slower rate; presumably quinone diffuses into the region where the dianion is and disproportionation occurs.

reduction is ceased. A reasonable interpretation involves protonation (from solvent impurities?) of the dianion. Although kinetic protonation should occur at oxygen, if the large strain energy<sup>6</sup> overrides the resonance energy<sup>3,4</sup> associated with the pyraclo system, tautomerization would occur to the more stable 1,2-diketopyracene. Further reduction of diketopyracene generates its radical anion, which is observed. This sequence is summarized below.

The formal reverse process, enolization of III to form VI, could have occurred in potassium *t*-butoxide-DMSO, but does not; VI would have oxidized to form II under our conditions and no II was observed. We have been unable to demonstrate that diketopyracene can tautomerize to dihydroxyacetylene.

#### Molecular Orbital Calculations

HMO calculations of the spin densities of II were performed to examine the agreement of predictions with experiment. Although simple HMO theory does not work particularly well for nonalternant systems (such as IV),<sup>9</sup> II is a special case, in this as in so many other respects. The odd-electron MO, the only one which normally is considered for esr spectra, has zero electron density at carbons 13 and 14. Thus, for the purposes of esr, this molecule can be considered an alternant system.

Values for the Coulomb integral at oxygen and the C-O resonance integral are required. By convention,<sup>14</sup> these are expressed as  $\alpha_O = \alpha_C + h_0\beta_{CC}$ ,  $\beta_{CO} = k_{CO}\beta_{CC}$ , respectively. Various  $h$  and  $k$  parameters have been used; values of  $h = 1.2$ ,  $k = 1.6$  gave the best fit in McLachlan calculations on *p*-quinones,<sup>9</sup> while  $h = 0.8$ ,  $k = 1.0$  fit several properties of unsaturated ketones best.<sup>15</sup> For II there is another criterion for choosing  $h$  and  $k$  besides best fit to coupling constants. As  $h$  and  $k$  are varied, the energy levels of the first two empty molecular orbitals cross. With  $h = 0.8$ ,  $k = 1.0$ , the ninth MO (antisymmetric with respect to the  $C_{13}-C_{14}$  axis,  $\psi_A$ ) is  $0.005\beta$  lower in energy than the tenth (symmetric,  $\psi_S$ ), but with  $h = 1.9$ ,  $k = 1.0$ ,  $\psi_S$  is  $0.030\beta$  lower than  $\psi_A$ . While  $\psi_A$  gives reasonable spin densities for any reasonable  $h$  and  $k$ ,  $\psi_S$  does not ( $\psi_S$  has almost zero spin density at position b and much higher spin density at oxygen). At constant  $k$ , increasing  $h$  lowers  $\psi_S$  much more than  $\psi_A$ , causing the crossing. The observed  $a$  and  $g$  values show the odd electron is in  $\psi_A$ . Figure 2 illustrates the energy level crossing.

(14) Reference 2, Chapter 4.

(15) H. E. Zimmerman, private communication.

ues of  $h$  and  $k$  were varied to find values for best the observed splitting constants. If the electron placed in  $E_A$  regardless of the energy crossing, a 1 the  $h$  vs.  $k$  plot for best fit (which is very good, 13 deviation from experiments for all densities) ntirely in the crossed region (Figure 2). Table III

### III. Calculated Spin Densities for Pyraclosemiquinone (II)

ickel energies crossed. Calculation at crossing of Hückel levels gives  $\rho_A$  far too low,  $\rho_B$  far too high;  $\rho_C$  is quite insen- o  $h$  and  $k$ .

ins values near the crossing points, the best "un- ed" values. A similar line may be calculated for lectrolytic spectrum. Here the best fit line lies e "uncrossed region." McLachlan calculations<sup>16</sup> 1 allow for electron correlation do not improve the experiment. All of the energy levels, not just re involved in these calculations, so this could been expected. Best fit lines can be drawn for the achlan calculations as well; both lie in the crossed el energy level area of the  $h, k$  plot.

ally, a closed shell SCF calculation<sup>17</sup> (which gives rkable agreement with the ultraviolet spectrum?) spin densities slightly closer to experiment than est "uncrossed" Hückel calculations for the base rum, which we assign to the "free" anion. e above discussion assumes constant  $Q$ 's at all ions to get the "experimental" spin densities. ukel<sup>18a</sup> and Higuchi<sup>18b</sup> have calculated that  $Q_H$  ases if the C-CH-C angle is decreased. Recent <sup>19</sup> has shown that for pyracylene anion (VIII) ,  $Q_b = 22.6$ ,  $Q_a = 30.0$ <sup>20</sup> are required to fit the rum using Hückel spin densities. Since bond s at position a of VIII and c of II should be similar,

VIII

A. D. McLachlan, *Mol. Phys.* 3, 233 (1960). We thank Pro- Holme for the use of his computer program for McLachlan cal- ns.

We are deeply indebted to Dr. Howard E. Simmons for this cal- n. This calculation shows that  $\psi_A$  is of lower energy than  $\psi_B$ . (a) I. Berual, D. H. Rieger, and G. K. Fraenkel, *J. Chem. Phys.*, 39 (1962); (b) J. Higuchi, *ibid.*, 39, 3455 (1963).

B. M. Trost, S. F. Nelsen, and D. Brittelli, to be published. This angle is estimated to be approximately 106°. Fraenkel's tion gives a  $Q$  of about 38 for this angle.

$Q = 30$  for position c of II might be expected. This would make  $\rho_c = 0.071$  for the base spectrum and 0.086 for the electrolytic spectrum, which improves agree- ment with the latter, but makes it worse for the former. Since  $\rho_T$  is very insensitive to  $h$  and  $k$  variations, chang- ing  $h$  and  $k$  does not account for using a larger  $Q$  at position c than positions a and b. The value of  $Q$  is claimed to be dependent upon charge density as well as bond angle. The Colpa and Bolton<sup>21</sup> modification of the McConnell equation,  $a_i = (Q' + k\epsilon_i)\rho_i$ , where  $\epsilon_i$  is the excess charge at position i, does not improve the fit, nor justify use of a larger  $Q'$  at position c than posi- tions a or b. The Giacometti modification,<sup>22</sup>  $a_H = Q_1\rho_1 - Q_2 |\sum_j c_{ij}c_j|$  where  $j$  are atoms bonded to  $i$ , does not produce significant changes from the regular Mc- Connell equation; to obtain as good a fit,  $Q_1$  must be about 24 instead of the 31.5 which fits best.

Thus the excellent agreement of simple Hückel theory with experiment using constant  $Q$ 's seems to be for- tuitous, since  $Q_c$  ought to be larger than  $Q_a$  and  $Q_b$ .

The esr spectrum of III was calculated using the method of Levy<sup>23</sup> to predict the methylene splitting constants. Table IV gives results for the extreme  $h_0$  and  $k_{CO}$  values used for II; agreement is considerably less favorable for the ring protons of III than II, as is expected.<sup>9</sup> The methylene splitting constants agree about as well as other examples.

Table IV. Calculated Spectrum for Diketopyracene Anion (III)

	Exptl	HMO, $Q = 24$ $h = 0.8,$ $k = 1.0$	HMO, $Q = 24$ $h = 1.2,$ $k = 1.6$	McLachlan
$a_a$	1.15	0.49	0.60	0.60
$a_b$	0.21	0.00	0.00	0.38
$a_c$ (methylene)	1.38	0.92 <sup>a</sup>	1.22 <sup>a</sup>	1.29 <sup>a</sup>

<sup>a</sup> Calculated by the method of Levy.<sup>23</sup>

Neither III nor IV shows the "base effect" on the splitting constants which is so prominent in the spec- trum of II, although geometry at the carbonyls must be very similar. We suggest that the greater resonance energy and lower oxygen charge density of II could allow free II to be formed in base, but not in III and IV, which would have stronger chelates (or tighter ion pairs) and thus are not as easily broken up.

In addition to the correlation of splitting constants with molecular orbital theory, Stone<sup>24</sup> developed a cor- relation of hyperfine splitting factors ( $g$  factors) with molecular orbital theory. For semiquinone anions, he found this relationship could be expressed by eq 1.<sup>25</sup>

$$\Delta g = b + \lambda c + \rho_o \gamma_o \quad (1)$$

Since the half-wave potential of the quinone also is re- lated to the energy coefficient ( $\lambda$ ) of the lowest unoc- cupied molecular orbital, this equation can be modified so that the  $g$  factor shift is expressed as a function of the

(21) J. P. Colpa and J. R. Bolton, *Mol. Phys.*, 6, 273 (1963).

(22) G. Giacometti, P. L. Nurdio, and M. V. Pavan, *Theoret. Chim. Acta*, 1, 404 (1963).

(23) D. H. Levy, *Mol. Phys.*, 10, 233 (1966).

(24) A. J. Stone, *ibid.*, 6, 509 (1962).

(25) In this equation,  $\Delta g$  is the difference between the observed  $g$  factor and that for a free electron, 2.00232;  $\lambda$  refers to the energy of the odd electron orbital of the semiquinone;  $\gamma_o$  is a function of  $\lambda$ ;  $\rho_o$  is the spin density at oxygen;  $b$ ,  $c$ , and  $\gamma_o$  are experimental constants.

Figure 3. A plot of  $\gamma_0$ , which is a function of the energy of the first unoccupied molecular orbital ( $\lambda$ ), vs. the half-wave potentials of the same quinones employed by Stone.<sup>24</sup>

half-wave potential and the oxygen spin density. Such a modification allows one to calculate the spin density at a heteroatom, oxygen, from two experimental quantities,  $g$  factors and half-wave potentials.

To examine this possibility, we undertook a study of the half-wave potentials of the same quinones chosen by Stone for his correlations.<sup>26</sup> For our polarographic studies, we employed DMSO as solvent since we had employed this solvent for our esr studies and since it gave the best polarographic results. The half-wave potentials ( $U_{1/2}$ ) are summarized in Table V. For the molecular orbital calculations, we chose the oxygen parameters suggested by Fraenkel as those giving best fit for esr spectra,  $h = 1.2$  and  $k = 1.6$ . Plotting  $\lambda$  vs.  $U_{1/2}$  for the first wave gives two straight lines, one for *o*-quinones (eq 2) and one for *p*-quinones (eq 3).<sup>27</sup>

$$\lambda = 0.626U_{1/2} + 0.115 \quad (2)$$

$$\lambda = 0.580U_{1/2} + 0.187 \quad (3)$$

Table V. Half-Wave Potentials of Selected Quinones\*

Quinone	Wave 1, v	Wave 2, v
1,4-Benzoquinone	-0.376	-1.174
1,4-Naphthoquinone	-0.550	-1.289
9,10-Anthraquinone	-0.784	-1.454
1,2-Benzoquinone <sup>b</sup>	-0.220	...
1,2-Naphthoquinone	-0.463	-0.772
9,10-Phenanthroquinone	-0.545	-1.277

\* Values reported are vs. a standard calomel electrode. <sup>b</sup> Assuming  $\Delta U_{1/2}$  on changing from DMF to DMSO is similar to that for the other quinones.

Since Stone's constant  $\gamma_0$  is a function of  $\lambda$ , we replotted  $\gamma_0$  in terms of half-wave potentials to obtain the two lines in Figure 3. Substituting these values into Stone's equations leads to eq 4 for *o*-quinones and eq 5

$$\Delta g = 22.5 \times 10^{-5} - 12.1 \times 10^{-5}U_{1/2} + \rho_0\gamma_0 \quad (4)$$

$$\Delta g = 21.1 \times 10^{-5} - 11.2 \times 10^{-5}U_{1/2} + \rho_0\gamma_0 \quad (5)$$

(26) For a similar correlation under a different set of conditions and employing different parameters of  $h$  and  $k$  for oxygen for molecular orbital calculations, see M. E. Peover, *J. Chem. Soc.*, 4540 (1962).

(27) Equations are for the best least-squares lines.

for *p*-quinones. The success of the method can be illustrated by the striking agreement between the spin densities obtained from eq 5 and Hückel spin densities for a series of *p*-quinones in Table VI. For the latter, best fit was not attempted; the oxygen parameters are those used in developing the equations (Fraenkel's best fit values) and the methyl group parameters are those suggested by Coulson and Crawford.<sup>28</sup>

Table VI. Spin Densities at Oxygen

Quinone	Eq 5 <sup>a</sup>	Hückel
2-Methylbenzoquinone	$0.33 \pm 0.03$	0.346
2-Methyl-1,4-naphthoquinone	$0.28 \pm 0.03$	0.228
Duroquinone	$0.38 \pm 0.03$	0.332

<sup>a</sup> Obtained employing the literature values for  $g$  factors and half-wave potentials,<sup>29</sup> the latter adjusted for change in solvent. The error is principally due to the uncertainty in the  $g$  factor.

Table VII summarizes the polarographic data and spin density calculations for the quinones of interest in this study. These data confirm the previous conclusion that the oxygens of pyraclosemiquinone anion bear extremely low spin density, approximately one-fifth that for normal semiquinone anions. Since presently we are unable to measure  $g$  factors more accurately, a large error exists in the spin densities calculated from eq 4.<sup>29</sup> Nevertheless, the quantitative agreement within our experimental error is excellent. These results in conjunction with the abnormally large hyperfine splitting constants of II indicate the unique nature of the pyracylene system and suggest its semiquinone anion is more akin to a hydrocarbon radical anion rather than a quinone radical anion. Theory and experiment and the excellent correlation between them attest to this conclusion.

## Experimental Section

**Materials.** The quinones, pyracloquinone and 1,2-diketopyracene, were prepared as previously described.<sup>6,7</sup> Acenaphthaquinone, *p*-benzoquinone, 9,10-phenanthraquinone, and 9,10-anthraquinone were obtained from Aldrich Chemical Co. 1,2-Naphthaquinone and 1,4-naphthaquinone were obtained from Eastman Kodak Co. Pyracloquinone-5,6-*d*<sub>2</sub> was prepared as described for the undeuterated compound<sup>6,7</sup> except acenaphthene-*d*<sub>4</sub> was employed in the initial step. Mass spectral analysis<sup>30</sup> indicated the deuterated compound was 97% *d*<sub>2</sub> and 3% *d*<sub>1</sub>. Dimethyl sulfoxide and dimethoxyethane were dried by distillation from calcium hydride. Tetra-*n*-butylammonium perchlorate was dried *in vacuo* at 68°. Tetra-*n*-butylammonium iodide was dried *in vacuo* at room temperature.

**Esr Determinations.** Esr spectra were recorded using a Varian V4502 instrument with a 9-in. magnet. Fremy's salt in saturated sodium carbonate was used as a calibration standard ( $g = 2.0055$ ,  $a_N = 13.0$  gauss) with dual cavity. The Varian electrolytic cell was used for *in situ* reductions. Solutions were deoxygenated by bubbling nitrogen through them and sample tubes were either 1-mm Pyrex capillaries or the Varian electrolytic cell. Ultraviolet irradiation was carried out using a Bausch and Lomb "high intensity" monochromator with Osram HBO-200W superpressure source.

(28) C. A. Coulson and V. A. Crawford, *J. Chem. Soc.*, 2052 (1953).

(29) It is important to point out that methods for more accurate  $g$  factor determinations are becoming available. The main source of error to the spin densities calculated by eq 4 and 5 is the uncertainty in this value.

(30) Mass spectral determinations were performed by Morgan-Schaeffer Corp., Montreal, Quebec, and by Professors Larry A. Singa and Joseph Ciabattini. We are deeply indebted to them for these determinations.

<sup>a</sup> See ref 4 for description of procedures and for definition of terms. All amino acids are of the L configuration. Within the limits of the technique all compounds shown in this table are optically pure. The molecular weight of the polymer is the residue weight. <sup>b</sup> The first number is the concentration in weight per cent. DMF is dimethylformamide. DMSO is dimethyl sulfoxide. DCA is dichloroacetic acid. <sup>c</sup> The first number is the number of independent samples; the second is the total number of rotations run. <sup>d</sup> Drude parameters. With these parameters it is a simple matter to run off the rotations at any wavelength within 589-365 m $\mu$  by use of a deck calculator. The results so obtained may be considered to be averages of our measurements and have precisions of the order of 0.1% and accuracies as specified in the last column. Also note that this is the per cent error, not the absolute error. The molecular weight is given to facilitate calculation of specific rotations. The large error limits of  $\alpha$  and  $\lambda_0$  are the result of their correlation. <sup>e</sup> Molar rotations. <sup>f</sup> Estimated per cent standard deviation of the calculated molar rotations =  $100s/Mn$ ;  $s$  is the standard deviation of the observed values;  $n$ , number of rotations run. Rotations run from 589 to 365 m $\mu$  unless noted. <sup>g</sup> Does not fit Drude; Moffitt (the Moffitt equation is used here merely as an empirical three-term Drude expression) parameters:  $a_0 = 354.49$ ,  $b_0 = -227.77$ ,  $\lambda_0 = 200.00$  (chosen arbitrarily). Any value of  $\lambda_0$  from 100 to 240 m $\mu$  is almost as good providing the correct corresponding values of  $a_0$  and  $b_0$  are used. <sup>h</sup> Does not follow Drude. Moffitt (the Moffitt equation is used here merely as an empirical three-term Drude expression)  $\pm a_0 = -47.748$  105,  $b_0 = 32.491 \pm 159$ ,  $\lambda_0 = 246.51 \pm 200$ . <sup>i</sup> The large standard deviations indicate that a wide selection of parameters work equally well. The cited values reproduce the calculated values to within about 0.1%, and these calculated values taken as averages of the observed values have a standard deviation of 10%. The large error is due to the fact that the observed  $\alpha$  values were small. <sup>j</sup> 105% of the values obtained on hydrolysis of Z-Ser(H)-OH. See text. <sup>k</sup> Optical purity by hydrolysis with 5 N HCl, 100°, 15 hr; rotation in 5 N HCl (c 2). <sup>l</sup> 100.9% (av of 2). <sup>m</sup> 589-435 m $\mu$ . <sup>n</sup> For optical purity see Table II.

The use of the *p*-nitrophenyl group as a carboxyl-blocking group required an extensive study of factors which affect the yield of product.<sup>2,8</sup> One preparative detail that should be mentioned is an unconventional order of mixing reagents: a solution of the acid and triethylamine is added to a suspension of the hydrobromide in a solution of the carbodiimide. Required rates of addition depend on the choice of solvent and are related to the rate of solution of the salt. It may also be noted that diisopropylcarbodiimide can often be used to advantage where the peptide product is difficult to separate from the very insoluble dicyclohexylurea.

The removal of the benzyloxycarbonyl group was carried out with hydrogen bromide in nitromethane or in dioxane solution since with acetic acid the serine was partly esterified. The tripeptide hydrobromide is difficult to purify but is readily converted to the *p*-toluenesulfonate 7 by mixing it with triethylammonium *p*-toluenesulfonate in methanolic solution.

(8) D. F. DeTar, R. Silverstein, and F. F. Rogers, Jr., *J. Am. Chem. Soc.*, **88**, 1024 (1966).

Polymerization was carried out in dimethyl sulfoxide or in dimethylformamide using the equivalent amount of triethylamine or of sodium *p*-nitrophenoxide as the base. The polymer was precipitated with chloroform or with methanol and was extracted with chloroform and with methanol. Some samples were dialyzed against water.

The optical purity of the intermediates and of the polymers was subjected to a careful study. For the peptides two criteria were used, the repeatability of the observed rotations for samples prepared by different techniques (summarized in Table I) and the rotations obtained after complete acid hydrolysis under carefully defined conditions. The hydrolysis technique has a repeatability of about 2%, and there is a further uncertainty of 2% in the rotation values assigned to L-serine. L-Z-Ser-OH provided a definitive serine standard subject to the assumption that loss of optical activity upon hydrolysis was the same as for serine itself (5%). It was possible to show that small amounts of DL-Z-Ser-OH can be removed from L-Z-Ser-OH by recrystallization from ethyl acetate.

The use of hydrolysis to estimate the optical purity of

tides containing both serine and aspartic acid is necessarily less accurate, but the results were still excellent. In Table II are given the expected molar rotations of aspartic acid and of serine appropriate to the hydrolysis conditions along with the rotations found for the tripeptides. Agreement is within the 3–4% limits specified.

TABLE II. Optical Purity of Peptides and of Polymers

These values are lower than the respective values reported for aspartic acid and for pure serine since they refer to hydrolysis obtained after heating at 100° for 15 hr in 5 N hydrochloric acid. This treatment leads to about 3% loss of activity in the aspartic acid and 5% in the serine. <sup>b</sup> Based on polymer purity of 92.8% estimated from elemental analysis. <sup>c</sup> Based on polymer purity of 92.8% estimated from elemental analysis. <sup>d</sup> Based on polymer purity of 89% estimated from elemental analysis. Assumed that the serine is 100% L, the aspartic acid has been racemized by triethylamine treatment and is 35% L and 65% DL. <sup>e</sup> Averages of two independent samples. <sup>f</sup> Average of five independent samples. <sup>a</sup> Purity 90.6%. <sup>b</sup> Purity 92.0.

The evaluation of the optical purity of the polymers is more difficult for they absorb such solvents as water and chloroform tenaciously, and do not lose solvent completely even on prolonged drying at 100° and 0.1 mm. The reported molar rotations (Table I) are based on the peptide content as estimated from elemental analysis. The error limits are estimated to be about 10% for the polymers. Conversion of TosOH-H-Asp(OCH<sub>3</sub>)-Ser(H)-Gly-ONP to polymeric imide by use of excess triethylamine (third from last line in Table I) led to a low rotation; racemization is presumably attributed to the aspartyl residue.

The fact that the polymer is only partly racemic suggests that imide formation is faster than racemization. This in turn permits the absence of racemization in the earlier polymer samples to be taken as a demonstration of the absence of such a process as reversible conversion of ester to imide. Such conversion, if it occurred, would lead to a mixture of  $\alpha$ - and  $\beta$ -aspartyl linkages. Hydrolysis of the methyl ester of poly Asp(OCH<sub>3</sub>)-Ser(H)-Gly by hydrolysis leads to imide formation, and the imide hydrolyzes to a mixture of  $\alpha$ - and  $\beta$ -aspartyl linkages.<sup>4,9</sup> An attempt was therefore made to remove the ester group by heating at 85° for 15 hr in lithium iodide in pyridine.<sup>10</sup> The resulting poly-

mer was dark in color and had about half of the ester groups removed.

Proton magnetic resonance of trifluoroacetic acid solutions of peptides and polymers proved most useful in structure verification. Important peak positions are summarized in Table III. Integrated areas agreed well with those expected.

Molecular weights were determined by end-group labeling and by the ultracentrifuge using the Archibald method. The determination of amino end groups by dinitrophenylation using the general procedure of Sanger requires a hydrolysis step and chromatographic isolation of the DNP amino acid. This was carried through on one sample of poly Asp(OCH<sub>3</sub>)-Ser(H)-Gly and it was found, as expected, that the only N-terminal residue is aspartic acid. However for estimating molecular weights, this procedure is tedious, involves hydrolytic loss of over half of the DNP-Asp(OH)-OH, and requires relatively large samples. A shorter procedure was therefore developed which involves spectrophotometric measurements directly on the DNP polymer. Details are given in the Experimental Section. Properties of the polymers are summarized in Table IV. The observed relationship between  $\bar{M}_w$  and intrinsic viscosity  $[\eta]$  is given by the expression  $\log [\eta] = 0.367 \log \bar{M}_w - 2.061$  with a variation in  $[\eta]$  from 0.15 to 0.28 and of  $\bar{M}_w$  from 2500 to 12,000. For condensation polymerization of the type used here the  $\bar{M}_w/\bar{M}_n$  is expected to be about 2.<sup>11</sup> Low values are believed to reflect in part the presence of cyclic material, a known by-product in these reactions.<sup>4</sup>

The rates of hydrolysis of the methyl ester and of the imide were investigated briefly at constant pH in the pH-Stat. Results were calculated for the rate expression  $-d[\text{ester}]/dt = k_2[\text{ester}][\text{OH}^-]$  and are only approximate since the reaction was somewhat less than pseudo first order in ester. Since the imide gave parallel results, the rate-limiting step is hydrolysis of the imide. At pH 9 in 0.4 M sodium chloride the initial rate constant for both ester and imide is about 200 l. mole<sup>-1</sup> sec<sup>-1</sup> at 25°. This value is comparable to that reported for Z-Asp(OBt)-Ser(H)-NH<sub>2</sub> (BENCASA),<sup>9</sup> and the polymeric structure seems to be providing no large special effect. It might be expected that there would be a retarding electrostatic effect of the neighboring carboxylate groups on the rate,<sup>12</sup> but this aspect has not been investigated.

The polymers were titrated quantitatively both before and after a very brief hydrolysis with 0.1 N sodium hydroxide and gave satisfactory agreement with theory. Values were corrected for polymer contents of 80–95% based on elemental analysis. The results are summarized in Table V.

The rate of hydrolysis of the acetate group of poly Asp(OH)-Ser(Ac)-Gly is of interest because of its close relationship to the acetylated form of chymotrypsin, trypsin, and other hydrolytic enzymes.<sup>13</sup> The second-order rate constant at pH 11.9 was found to be 0.1 l. mole<sup>-1</sup> sec<sup>-1</sup>. This may be compared with 0.07

## Experimental Section<sup>15-18</sup>

1. Z-Asp(OBI)-OH.<sup>19</sup> The following preparation has been repeated many times. A mixture of 70 g of Z-Asp(OH)-OH, 350 ml of benzene, 10 g of TosOH·H<sub>2</sub>O, and 100 ml of benzyl alcohol was refluxed until no more water was collected in a trap. The cooled mixture was shaken with 10 g of magnesium oxide for 10 min and filtered. Benzene and most of the benzyl alcohol were removed *in vacuo*. Trituration of the resulting oil with 200 ml of hexane gave 112 g of crystalline Z-Asp(OBI)-OBI, mp 61-63°.

The dibenzyl ester (112 g) was dissolved in a mixture of 1200 ml of dioxane and 500 ml of water and to this was added a mixture of 120 ml of 2 *N* sodium hydroxide solution, 700 ml of water, and 1200 ml of dioxane. After 24 hr at room temperature the pH was brought to 5.5 by adding a few drops of concentrated hydrochloric acid. Solvents were removed on the rotary evaporator, and the residue was

(15) Nitrogen analyses and rotations by Mrs. Lillian Ross.

(16) We are indebted to Carla Howard for the ultracentrifuge runs.

(17) Peptides are in indexing order, amino acids first, then dipeptides, tripeptides, polymers, alphabetic order from amino acid.

(18) For assays and general procedures see ref 4.

(19) This preparation was carried out by Drs. W. Honsberg and Frank Gilmore.

up in 240 ml of 1 *N* aqueous sodium bicarbonate and extracted ether to remove unreacted diester. Acidification gave an oil crystallized, 66 g (74%). Recrystallization from benzene 50 g (67%) of product, mp 102–103°. Further recrystallization with 60% recovery gave material with mp 106–108° (lit.<sup>20,21</sup>).

The infrared spectrum (137, oil) showed bands at: 1740, 1705, 1695, 1645, and 1530 cm<sup>-1</sup>.

**Z-Ser(H)-OH.**<sup>22,23</sup> This product has been prepared using methods for maintaining basicity: sodium bicarbonate, addition of sodium hydroxide, and magnesium oxide. Use of magnesium oxide is best for large-scale runs.

A mixture of 125 g of magnesium oxide, 2000 ml of water, and of serine was stirred and cooled to 5°, and 800 ml of ether was added. Then 264 g of benzyl chlorocarbonate was added, one-half immediately, one-half over 10 min, and one-fourth over 20 min.

The temperature was maintained at 5° throughout and for additional 2.5 hr. Filtration required a filter aid (Celite 535, a maceous earth). The ether layer of the filtrate was separated and the aqueous layer extracted with three 600-ml portions of ether then slowly added to 110 ml of cold concentrated hydrochloric acid.

The product separated as fine white crystals, 191 g, mp 98–100°. Extraction of the filtrate gave another 21 g, mp 103–105°.

The product was further purified by recrystallization from 550 ml ethyl acetate and then from 500 ml of water to give eventually 100 g of product, mp 114–116°. Ethyl acetate is a convenient solvent for estimating optical purity (see Table I).

**Z-Asp(OCH<sub>3</sub>)-Ser(Ac)-OH.** A mixture of 8.04 g of Z-Asp(OCH<sub>3</sub>)-ONP, 3.67 g of HCl-H-Ser(Ac)-OH, and 6.06 g of triethylamine in 50 ml of acetone was allowed to stand for 18 hr at room temperature.

The solvent was evaporated; the residue was taken up in ether, and the solution acidified with hydrochloric acid and extracted with ethyl acetate six times. The ethyl acetate was dried, concentrated in volume to 60 ml, and diluted with 120 ml of hexane to give 1.1 g (87%) of white crystals, mp 132–134°. Recrystallization from the same solvent gave mp 141–142°.

*Anal.* Calcd for C<sub>15</sub>H<sub>21</sub>N<sub>3</sub>O<sub>8</sub>: C, 52.68; H, 5.40; N, 6.83; wt, 410.4. Found: C, 52.6; H, 5.60; N, 7.00; mol wt by phase osmometer, ethanol, 389, 395.

**HBr-H-Ser(H)-Gly-ONP.** In 1500 ml of methylene chloride (distilled from phosphorus pentoxide) was suspended 84.4 g of Ser(H)-Gly-ONP. Dry hydrogen bromide was introduced at a slow rate. Within 3 min the suspension thickened and stirring became difficult. After 15 min evolution of carbon dioxide began. Hydrogen bromide was introduced for another 1.5 hr, during which time the thick mixture transformed into an easily stirred suspension. Reaction was judged complete when no material less than methylene chloride was present. Dry air was then drawn through for 0.5 hr and then the product was filtered and dried with several 200-ml portions of acetonitrile; yield 66.0 g (70%), mp 170.5–171.5°. The product can be recrystallized by dissolution in a minimum quantity of hot DMF followed by a tenfold excess of hot acetonitrile, mp 173–173.5°. Only one spot was found by thin layer chromatography on acidic silica gel using 20% methanol in methylene chloride.

*Anal.* Calcd for C<sub>11</sub>H<sub>14</sub>N<sub>2</sub>O<sub>8</sub>Br: C, 36.30; H, 3.88; N, 11.55; Br, 5.38; Br, 21.90; ONP, 37.94. Found: C, 36.28; H, 3.87; N, 11.53, 11.57; O, 26.65; Br, 22.11; ONP, 37.6, 38.0.

**Z-Ser(H)-Gly-ONP.** A detailed study of this reaction has been reported by Rogers.<sup>2</sup> To a solution of 49.5 g (0.24 mole) of lohexylcarbodiimide in 600 ml of acetonitrile cooled to 5° was added 66.6 g (0.24 mole) of HBr-H-Gly-ONP. The suspension was vigorously stirred and immediate addition begun of a solution of 10.25 g (0.25 mole) of Z-Ser(OH)-OH and 31.8 ml (0.23 mole) of triethylamine in 200 ml of acetonitrile. The rate of addition was adjusted to require 8 min. The mixture was stirred at ice-bath temperature for 1 hr with addition of 400 ml of acetonitrile to facilitate stirring. 2 hr more at room temperature, the mixture was filtered. The solid was stirred with a 250-ml portion of warm (40°) dimethylformamide, and the insoluble portion was extracted with another 100-ml portion. The DMF solutions were allowed to stand for 15 min at room temperature to allow precipitation of salts of DCU. Upon addition of 300 ml of cold 0.01 *N* HCl followed by 200 ml of water, the product precipitated and was filtered after about 30 min, 68 g, mp 161–162°. The acetonitrile filtrate yielded a second crop upon evaporation to dryness and tri-

thylamine was removed with 100 ml of methanol, 7.5 g, mp 157–158°. The total crude yield was 75%. Recrystallization from 350 ml of 1:3 DMF-methanol gave 62.3 g (83% recovery) of colorless material, mp 170–171°.

Thin layer chromatography on acidic silica gel with 4% methanol in methylene chloride gave a single yellow spot when sprayed with dilute alkali.

*Anal.* Calcd for C<sub>15</sub>H<sub>19</sub>N<sub>3</sub>O<sub>8</sub>: C, 54.67; H, 4.60; N, 10.07; O, 30.65; ONP, 33.09. Found (2 samples): C, 54.30, 54.48; H, 4.67, 4.53; N, 10.12, 10.58; O, 30.65, 30.24; ONP 33.2, 32.7.

**6. HBr-H-Asp(OH)-Ser(Ac)-Gly-ONP.** A freshly prepared 3.8 *M* solution of hydrogen bromide in acetic acid (50 ml) plus 2.5 ml of acetic anhydride was placed in a pressure-equalized addition funnel and added rapidly with stirring to 6.25 g of Z-Asp(OH)-Ser(H)-Gly-ONP. The material dissolved and during the next 15 min gas evolution (CO<sub>2</sub>) was observed. After a total reaction time of 4 hr, 100 ml of ether was added. This caused precipitation of a gum. The solvent was decanted and 100 ml more ether was added. The solvent was decanted from the partly crystalline material. This was dissolved in 30 ml of acetonitrile and ether added to precipitate a sticky product. The residue was again dissolved in 30 ml of warm acetonitrile and then began to crystallize; yield 2.4 g of nonhydroscopic white powder, mp 141–142°. Extraction with 40 ml of hot acetonitrile gave 2.2 g of material, mp 143–144.5°.

*Anal.* Calcd for C<sub>17</sub>H<sub>21</sub>N<sub>4</sub>O<sub>10</sub>Br: C, 39.17; H, 4.06; N, 10.75; O, 30.69; Br, 15.33; ONP, 26.50. Found: C, 38.72; H, 4.11; N, 10.61; O, 30.58; Br, 15.37; ONP, 25.9.

**7. TosOH-H-Asp(OCH<sub>3</sub>)-Ser(H)-Gly-ONP.** Z-Asp(OCH<sub>3</sub>)-Ser(H)-Gly-ONP (20 g) was placed in a 1-l. flask fitted for introduction of hydrogen bromide and 400 ml of reagent grade methylene chloride was added. During 1.5 hr, a stream of hydrogen bromide was introduced. A thick suspension formed and this changed to a fine suspension. The product was filtered (hygroscopic) and washed with two portions of methylene chloride and then with two portions of ether. It was then dissolved in 200 ml of methanol and precipitated with 1500 ml of ether. The material solidified upon standing overnight at 0°, 15.9 g of material with an ill-defined melting point. Attempts to get better material were not successful.

It was found practical to form the toluenesulfonate. The above product was dissolved in 75 ml of methanol and 30 g of triethylammonium *p*-toluenesulfonate was added. Removal of solvent on the rotary evaporator gave an oil. This was dissolved in 200 ml of acetonitrile; the solvent was removed and redissolved in 150 ml of acetonitrile. Upon scratching with a glass rod crystals separated; yield 13.8 g, mp 145–147°. The salt was dissolved in a mixture of 10 ml of hot dimethylformamide plus 10 ml of acetonitrile. Addition of 100 ml of hot acetonitrile gave an immediate separation of crystals, 12.4 g (58%), mp 150–151°. Chromatography (thin layer) on acidic silica gel G using 20% methanol in methylene chloride showed a single spot with alkaline spray.

*Anal.* Calcd for C<sub>23</sub>H<sub>28</sub>N<sub>4</sub>O<sub>13</sub>S: C, 47.25; H, 4.83; N, 9.58; O, 32.84; S, 5.49; OCH<sub>3</sub>, 5.31; ONP, 23.6. Found: C, 46.91; H, 5.03; N, 9.44; O, 32.69; S, 5.45; OCH<sub>3</sub>, 5.64; ONP, 23.3. Three other samples gave N, 9.30, 9.30, 9.36; ONP, 24.0, 23.3, 23.2.

**8. Z-Asp(OCH<sub>3</sub>)-Ser(H)-Gly-ONP.** (This preparation was carried out more than 20 times.)<sup>3</sup> This is a modification of the preparation of Z-Ser(H)-Gly-ONP. To a stirred solution of 22.4 g (0.108 mole) of DCC in 600 ml of acetonitrile, cooled in an ice bath, was added 37.4 g (0.103 mole) of HBr-H-Ser(H)-Gly-ONP and then there was added a solution of 33.3 g (0.118 mole) of Z-Asp(OCH<sub>3</sub>)-OH and 14.4 ml (0.103 mole) of triethylamine in 200 ml of acetonitrile at a uniform rate over a period of 1 hr. The proportions of reagents, their purity, and the rate of addition all affect the yield of product.

The resulting thick suspension was filtered, and the solid was extracted with two 100-ml portions of dimethylformamide containing 1 ml of 0.2 *N* HCl. The combined filtrates were concentrated to 300 ml in the rotary evaporator (flask temperature 40°). This was stirred while 300 ml of a slurry of ice in 0.01 *N* HCl was added slowly. This gave a moderately rapid precipitation of a white product. Then 500 ml of ice water was added and the material collected, 33.4 g, mp 176–179°.

The urea was extracted with an additional 100 ml of dimethylformamide and the product precipitated with 200 ml of ice water. The product was converted to a manageable solid by addition of 100 ml of methanol, yield 16.3 g, mp 183–185°, total yield 88%. The combined crops were stirred with 250 ml of hot methanol for 30 min and filtered, 46.5 g (78%), mp 186–188°. For analysis the material was recrystallized from ethyl acetate to give a product, mp 187–188°. This gave a single spot (alkaline spray) upon thin layer

chromatography on acid silica gel G with 5% methanol in methylene chloride.

*Anal.* Calcd for  $C_{24}H_{32}N_4O_{11}$ : C, 52.75; H, 4.80, N, 10.26; O, 32.22;  $OCH_3$ , 5.68; ONP, 25.3. Found (2 samples): 52.77, 52.69; H, 4.86; 4.96; N, 10.24, 10.23; O, 32.45, 34.20;  $OCH_3$ , 6.00, 5.90; ONP, 24.8, 25.2.

9. **Z-Asp( $OCH_3$ )-Ser(Ac)-Gly-OBI.** A mixture of 3.7 g of Z-Asp( $OCH_3$ )-Ser(Ac)-OH, 3.04 g of TosOH-H-Gly-OBI, 3.81 g of CMC, 1.25 ml of triethylamine, and 50 ml of chloroform was stirred for 3 hr at 20°. The solvent was evaporated; the residue was extracted with acetone and the insoluble urea removed by filtration. The acetone was removed, and the residue was taken up in ethyl acetate, washed with water, 1 *N* sodium bicarbonate, 3% hydrochloric acid, and water, and dried over magnesium sulfate. Addition of hexane caused precipitation of 2.5 g (50%) of product, mp 122–125°. Recrystallization from ethyl acetate–hexane gave mp 135–136°.

*Anal.* Calcd for  $C_{27}H_{31}N_5O_{10}$ : C, 58.16; H, 5.60; N, 7.54; mol wt, 557.5. Found: C, 58.1; H, 5.41; N, 7.08, 7.50, 7.60; mol wt (osmometer, ethanol), 530, 561.

10. **Z-Gly-Ser(H)-Gly-ONP.** This preparation was similar to that of Z-Asp( $OCH_3$ )-Ser(H)-Gly-ONP: to 7.15 g of DCC in 150 ml of acetonitrile was added 12.2 g of HBr-H-Ser(H)-Gly-ONP, cooled to ice temperature, then a solution of 7.83 g of Z-Gly-OH and 4.62 ml of triethylamine in 60 ml of acetonitrile was added over 1 hr. The infrared curve indicated 8% remaining DCC and anhydride peaks at  $1830\text{ cm}^{-1}$ . After another 30 min only 2% of DCC remained, and the anhydride peaks remained. One milliliter of 1 *N* HCl was added; the urea was removed by filtration and washed with 25 ml, and twice the volume of iced methanol (pH 1) was added to give 4.25 g of product, mp 178–180°. Another 7.4 g was obtained from the urea by extraction with 25 ml of DMF and precipitation by addition of 50 ml of iced methanol, total yield 67%. The former fraction was taken up in 8 ml of hot DMF and precipitated with 40 ml of hot acetonitrile to give 3.1 g of material, mp 195°. The latter had mp 195–196° as isolated.

*Anal.* Calcd for  $C_{24}H_{32}N_4O_9$ : C, 53.16; H, 4.68; N, 11.81; O, 30.35; ONP, 29.1. Found: C, 53.33; H, 4.80; N, 11.92; O, 30.91; ONP, 29.1.

11. **Z-Asp(OBI)-Ser(H)-Gly-ONP.** This preparation was carried out similarly to the preparation of Z-Asp( $OCH_3$ )-Ser(H)-Gly-ONP. To 13.6 g of DCC (0.065 mole assuming 98.5% purity) in 200 ml of acetonitrile was added 23.6 g (0.065 mole) of HBr-H-Ser(H)-Gly-ONP and then a solution of 26.6 g (0.074 mole) of Z-Asp(OBI)-OH and 9.8 ml (0.065 mole) of triethylamine in 50 ml of acetonitrile over 75 min. Addition of 150 ml of acetonitrile was necessary to permit stirring. The reaction was allowed to proceed for 1 hr with removal of the ice bath after the addition was complete. An infrared curve of the supernatant liquid showed that 98% of the DCC had disappeared, and there was still a small absorption at  $1830\text{ cm}^{-1}$ . The work-up was also similar to that for the methyl ester: 100 ml and then 30 ml of DMF containing 1 ml of 0.1 *N* HCl per 100 ml was used to extract the filter cake. The crude product was dissolved in 80 ml of hot 50:50 dimethylformamide–methanol, filtered to remove a small amount of solid, 300 ml of hot methanol added, and the suspension allowed to cool, yielding 25.2 g of soft needles, mp 161–162°. Recrystallization from a DMF–acetonitrile mixture gave a product which melted at 148° and then resolidified and melted again at 162°. Both forms have the same rotation in DMF. The product gave a single spot (alkaline spray) when chromatographed (tlc) on acidic silica gel G with 5% methanol–methylene chloride.

*Anal.* Calcd for  $C_{30}H_{38}N_4O_{11}$  (two samples for N and ONP): C, 57.87; H, 4.86; N, 9.00; O, 28.27; ONP, 22.2. Found: C, 58.27; H, 4.95; N, 9.18, 9.10; O, 27.83; ONP, 22.2, 21.5.

**Polymerization of H-Asp( $OCH_3$ )-Ser(Ac)-Gly-OH.** To a solution of 0.2–0.3 g of the tripeptide acid in 5 ml of dimethylformamide, DCC (1–2 equiv) was added. Evaporation of the solvent and extraction with water gave low molecular weight material (about 750, equivalent to 2.5 tripeptide units). This line was not pursued for reasons indicated in the discussion.

**Poly Asp( $OCH_3$ )-Ser(H)-Gly.** a. **Use of Triethylamine and Dimethyl Sulfoxide.** A solution of 7.8 g of TosOH-H-Asp( $OCH_3$ )-Ser(H)-Gly-ONP was prepared in 10 ml of dimethyl sulfoxide (DMSO) by slight warming. This was cooled to room temperature and stirred while 1.87 ml of triethylamine was added over a period of 2 min. During the next 10 min an unstirrable gel formed. This was stored for 4 hr, and addition of 10 ml of DMSO redissolved the gel. The mixture was stored in the dark for 4 days and the polymer precipitated by slow addition of 100 ml of chloroform.

The polymer was extracted with chloroform, methanol, and ether. It was dried at 50°, then over  $P_2O_5$  at 95° (0.3  $\mu$ ) for 16 hr to give 3.07 g of polymer (84%).

This material was subjected to further purification by suspension in DMSO (gel) which was centrifuged at 10,000 rpm; this was repeatedly suspended in chloroform and centrifuged. After drying, it was extracted with chloroform in a Soxhlet extractor and dried for 24 hr at 100° and 0.1 mm against  $P_2O_5$ .

*Anal.* Calcd for  $C_{10}H_{11}N_2O_6$ : C, 43.95; H, 5.53; N, 15.38, O, 35.13;  $OCH_3$ , 11.36. Calcd for  $C_{10}H_{11}N_2O_6$  plus 8.2% of  $CHCl_3$  and 1.8% of inorganic residue: C, 40.3; H, 5.04; N, 13.83, O, 31.6,  $OCH_3$ , 10.22; Cl, 7.3; residue, 1.8. Found: C, 39.9; H, 5.07; N, 13.7; O, 32.4;  $OCH_3$ , 10.2; Cl, 7.3; residue, 1.8.

b. **Use of Sodium *p*-Nitrophenoxide.** To a solution of 0.346 g of dried sodium *p*-nitrophenoxide (in oven at 110°) in 2 ml of DMSO was added 1.26 g of TosOH-H-Asp( $OCH_3$ )-Ser(H)-Gly-ONP. Within 30 min the mixture gelled. After 50 hr at room temperature, the polymer was precipitated by addition of 25 ml of methanol. It was washed with methanol and acetonitrile and dried at 70° over  $P_2O_5$  to give 0.44 g of polymer. Several samples were combined and dialyzed against water. After drying, the analysis was: C, 43.7; H, 6.14; N, 14.13; O, 35.99;  $OCH_3$ , 9.4.

**Rotation of L-Serine.** Literature values of the rotation of serine are insufficiently precise to permit a definitive assay of optical purity. Different lots of commercial serine (Nutritional Biochemicals) showed rotations of 80–97% of the values of pure L-serine as determined below and even lower purities were suggested by comparison with certain literature values. Since nitrogen assays were theoretical (13.32 found vs. 13.33 theory), the presence of considerable DL-serine was indicated.

Fortunately it was discovered that fairly pure L-Z-Ser(H)-OH can be recrystallized from ethyl acetate to give optically pure material. Among several samples which gave rotations close to those summarized in Table I, one had mp 118–119° when the capillary was placed in the bath at 100° and with the temperature rising 3°/min. A DL sample under these conditions showed mp 124–125°. A series of mixtures was made up containing 5, 10, and 20% of DL-Z-Ser(H)-OH, the remainder being the purest sample of L isomer available. The first crops obtained upon recrystallization from ethyl acetate showed melting points of 116–117, 115–117, and 113–116° and rotations, 100, 98, and 89% of the best values.

Other reference compounds containing serine were available for comparison; HBr-H-Ser(H)-Gly-ONP, e.g., prepared by three different workers in our laboratories had rotations within 1% of the average value. The concordance of rotations of such samples prepared at different times is good evidence that all are optically pure.

The rotation of pure L-serine was estimated by controlled hydrolysis of various serine derivatives with 5 *N* HCl (15 hr at 100°). This procedure gives values with some scatter, about 5% from the average, but with a common average. Similar treatment of serine itself gave a 2% scatter and a 5% loss of activity. The reported values for pure serine in Table I are based on the averages of several different types of samples and on the assumption that the average of the hydrolyzed samples is to be increased by 5% to compensate for loss. These resulting rotation values are appreciably lower than those tabulated by Greenstein and Winitz.<sup>14</sup> We believe the reported values to be too high; they correspond fairly well with our measurements in 1 *N* HCl.

**Identification of End Groups by Dinitrophenylation.** The modification by Porter of Sanger's method of identifying end groups was used as a basis for examining one polymer (RC-50-A) both for molecular weight and for identity of the end group. Poly Asp( $OCH_3$ )-Ser(H)-Gly (29.2 mg) and 50 mg of sodium bicarbonate were dissolved in 2 ml of distilled water by warming to 50°. The solution was cooled to room temperature, and a solution of 6.5 mg of dinitrofluorobenzene in 2 ml of ethanol was added. After 3 hr, 0.1 ml of concentrated aqueous ammonia was added and 15 min later the solvent removed. The residue was refluxed for 12 hr with 10 ml of 6 *N* hydrochloric acid, diluted to 25 ml with distilled water, and a 10-ml aliquot taken for assay.

The DNP-aspartic acid and other products were extracted with ethyl acetate, and the residue from the ethyl acetate was taken up in chloroform and chromatographed on a 2 × 0.5 in. column of silica gel which had been treated with a 15% by weight acetic acid–sodium acetate buffer. The first yellow band consisted of dinitro-

(24) J. P. Greenstein and M. Winitz, "Chemistry of the Amino Acids," John Wiley and Sons, Inc., New York, N. Y., 1961, p 116.

aniline as determined by thin layer chromatography on silica gel G, buffered with acetic acid-sodium acetate, and with ethanol-0.22 M ammonia (89:11) as eluent,  $R_f$  0.77. The second yellow band was eluted from the column with ether-methanol-acetic acid (49:49:2.5), and on thin layer chromatography as above had  $R_f$  0.12. This is the value found for DNP-aspartic acid. There were no traces of DNP-serine ( $R_f$  0.36), nor of DNP-glycine ( $R_f$  0.55) in any fraction.

The DNP-aspartic acid was taken up in 25 ml of a sodium borate buffer and absorbance read at 361  $m\mu$ . When the above procedure starting with the hydrochloric acid hydrolysis was carried out on pure DNP-aspartic acid, it was found that recovery was only 48%. Losses have been noted before during the hydrolysis steps.

The calculated number-average molecular weight, correcting for the loss, was 7200.

**Number-Average Molecular Weights by Dinitrophenylation.** An appropriate weight of sample (1-6 mg) was dissolved in 2 ml of 2% sodium bicarbonate, warming if necessary to effect solution. To this was added 2 ml of a freshly prepared 1-3% solution of 2,4-dinitrofluorobenzene in ethanol. After 2 hr at room temperature the solution was transferred quantitatively to a separatory funnel using 6 ml of 3 N hydrochloric acid for rinsing. The solution was extracted with two 10-ml portions of carbon tetrachloride and the aqueous layer filtered through wet filter paper into a 25-ml volumetric flask and diluted to volume with 3 N hydrochloric acid. Absorbance was read at 353  $m\mu$ . A blank run was used to correct for absorbance owing to dissolved carbon tetrachloride or other substances. Sample size was chosen to give an absorbance of about 0.8, and an extinction coefficient of  $1.59 \times 10^4$  l. mole<sup>-1</sup> cm<sup>-1</sup> was used. The rationale is that the extinction coefficient of the DNP derivatives may be expected to be relatively insensitive to the amino acid or the peptide to which the DNP is attached. In support of this it was found that five samples of DNP-Asp(OH)-OH in 2% sodium bicarbonate and in hydrochloric acid ranging from 1.2 to 6 N all had an extinction coefficient at 353  $m\mu$  of  $1.59 \times 10^4$  with a standard deviation of 0.022 per run or 0.01 for the average. The value for DNP-Gly-Gly-Gly-OH was 1.60. Values reported at 350  $m\mu$  for DNP-Gly-OH (1.55), DNP-Phe-OH (1.57), DNP-Gly-Gly-OH (1.58), DNP-Phe-Val-OH (1.55), and for H-Lys-(DNP)-OH (1.49) are close.<sup>24</sup> (All values are to be multiplied by 10<sup>4</sup>.) Properties of the polymers are summarized in Table IV.

$$\bar{M}_n = \text{mg of sample} \times$$

$$1.59 \times 10^4 / (A_{\text{sample}} - A_{\text{blank}})(\text{volume in milliliters})$$

**Weight-Average Molecular Weights from Ultracentrifuge Measurements.** The data in this paper are based on the Archibald method using the Beckman-Spinco Model E ultracentrifuge.<sup>26</sup> Runs were made in aqueous solution (mostly in 0.01 M KCl, but sometimes in water alone with comparable results) and at a concentration of 0.5-1%, usually using a Schlieren angle of 70° (50-85°) and a speed of 12,590, 20,410, or 24,630 rpm with photographs at intervals ranging from 10 to 100 min. In most cases only the meniscus values were used.

The principal source of error is the estimation of the intercept at the meniscus, and the error arises both from the problem of accurately identifying the meniscus and from the fading of the pattern. In the present series the meniscus was taken as the boundary as it appeared on the photographic plate, and extrapolation procedures were used to get the  $(dc/dx)_0$  value at this point. Plots of several sets of data showed that the arbitrary function  $\log (dc/dx)$  gave good agreement with the visual estimated of  $(dc/dx)_0$  and that parabolic extrapolation was less satisfactory. Errors arising from  $(dc/dx)_0$  estimates are the major source of the roughly 10% standard deviation per exposure. Data were processed by the computer program ARCHBD.

The calculated molecular weight is sensitive to the assumed density of the polymer, or of its reciprocal, the partial specific volume  $\bar{V}$ . Estimates of solution densities at concentrations of 1% with a precision of 1 part in 5000 lead to a 25% error in  $\bar{V}$ . We therefore used a calculated value for  $\bar{V}$  of 0.61 for poly Asp(OCH<sub>3</sub>)-Ser(H)-Gly.<sup>27</sup> The weight-average molecular weights in this paper have an estimated accuracy of about 20%. All data have been processed in a uniform fashion so that comparisons between samples involve only the standard deviation of the scatter which is 10%. Control runs on ribonuclease gave much sharper curves and satisfactory agreement with published results.

## Halide Ions as Probes for Nuclear Magnetic Resonance Studies of Proteins. The Sulfhydryl Groups of Hemoglobin

Thomas R. Stengle<sup>1</sup> and John D. Baldeschwieler

Contribution from the Department of Chemistry, Stanford University, Stanford, California. Received January 21, 1967

**Abstract:** Chlorine nmr spectroscopy is used to verify that the unreactive sulfhydryl groups of hemoglobin are incapable of forming structures of the type protein-S-HgCl even when the protein is dissociated in media of high ionic strength or low pH. However, dissociation of hemoglobin into fragments appears to be accompanied by conformational changes that restrict the motion of chlorine ions bound to mercury atoms complexed at the sites of the reactive sulfhydryl groups. The changes in structure and chemical reactivity of hemoglobin in urea solution are complex.

In recent years there has been a great deal of interest in the application of nmr techniques to systems of biological importance.<sup>2</sup> Since the direct application of nmr to proteins in solution is seldom fruitful, several indirect methods involving relaxation effects have been

developed.<sup>3,4</sup> Recently Stengle and Baldeschwieler<sup>5</sup> reported a novel technique which involves the use of a halide ion (usually chloride) as a probe for the study of mercury complexes of proteins. In this paper, this

method is applied to a specific protein, hemoglobin, with the aim of developing some information on the behavior of the sulfhydryl groups.

An interesting property of the hemoglobin molecule is its ability to dissociate into halves when dissolved in certain media. This phenomenon has been extensively investigated since it serves as a model for a variety of protein reactions.<sup>6</sup> From the nature of the media capable of causing dissociation it seems that the forces holding the halves together are primarily electrostatic, whereas further dissociation or unfolding, often leading to denaturation, must also involve the rupture of hydrophobic bonds.<sup>7,8</sup> The problem of the function of the unreactive sulfhydryl groups has been intimately connected with this aspect of the tertiary structure. There is some evidence to indicate that the unreactive sulfhydryl groups are directly involved in the interchain linkage,<sup>9</sup> although other work has not substantiated this contention.<sup>8</sup> This question can be resolved by a study of the SH groups of the dissociated molecule. If dissociation exposes originally unreactive SH groups to the solvent, hence activating them, the inference is that they are involved in the interchain binding. However, if the unreactive SH groups remain unreactive when the protein is cleaved, they must not be involved in interchain binding. Cecil and Thomas<sup>8</sup> studied the unreactive SH groups in a mixed water-alcohol solvent which was designed to rupture hydrophobic bonds without causing dissociation of the hemoglobin molecule. They found that the addition of alcohol to the solvent did cause an enhancement of the SH reactivity, indicating that the SH groups were involved in hydrophobic bonding and, hence, in intrachain structure.

Since the halide ion nmr technique can be specific for SH groups, it can be used to verify and extend the earlier results. The nmr method is particularly appropriate since it examines reactive SH groups, whereas Cecil and Thomas<sup>8</sup> worked with the unreactive ones.

### Theory

For a nucleus of spin greater than  $1/2$  (e.g.,  $^{35}\text{Cl}$ ,  $^{79}\text{Br}$ ,  $^{127}\text{I}$ ) the interaction of the nuclear electric quadrupole moment,  $Q$ , with the fluctuating field gradient,  $q$ , at the nucleus can provide a simple and dominant relaxation mechanism. In the extreme narrowing approximation, the contribution to the nuclear resonance line width from quadrupole relaxation is

$$\Delta\nu = K(e^2qQ)^2\tau_c \quad (1)$$

where  $\Delta\nu$  is the full line width at half-height in cycles per second,  $e^2qQ$  is the quadrupole coupling constant in cycles per second,  $\tau_c$  is the correlation time for molecular rotation in seconds, and  $K$  equals  $2\pi/5$  for a nucleus of spin  $3/2$  if the asymmetry parameter is neglected. A large range of line widths is possible depending on the values of these quantities. For example, for a chloride ion in dilute aqueous solution, the solvation of the ion is essentially symmetric, and the electric field gradient at the nucleus is nearly zero. This results in a line width of 15–20 cps for the  $^{35}\text{Cl}$

signal in aqueous solutions of NaCl. However, when the chlorine atom is involved in covalent binding, the value of  $e^2qQ$  is quite large; the line width for  $\text{CCl}_4$  is 14.5 kc/sec. Even greater line widths are expected for molecules larger than  $\text{CCl}_4$  with longer  $\tau_c$ .

If a quadrupolar nucleus can be located at different kinds of sites in solution, the resulting line shape depends on the relative concentrations of the various sites, the values of  $e^2qQ$  and  $\tau_c$  at each site, and the rate of exchange of chlorine among the various sites. If there are two possible sites, and the exchange of chlorine between them is very rapid, the spectrum will be a single composite signal of line width

$$\Delta\nu = \Delta\nu_a P_a + \Delta\nu_b P_b \quad (2)$$

where  $\Delta\nu_a$  and  $\Delta\nu_b$  are the line widths at sites a and b, and  $P_a$  and  $P_b$  are the probabilities that the nucleus is at sites a and b. It is apparent from eq 2 that if  $\Delta\nu_b$  is very large, a very small value of  $P_b$  may produce an observable effect on the line width  $\Delta\nu$ . Hence the chloride ion can be used as a probe for interesting sites in low concentrations, and the exchange process functions as a chemical amplifier. For small values of  $P_b$ ,  $P_a \cong 1$  and

$$\Delta\nu - \Delta\nu_a \cong \Delta\nu_b P_b \quad (3)$$

The conditions for the binding and exchange process are reasonably restrictive. The chloride ion must be able to enter the first coordination sphere of the site and form a sufficiently strong bond to give a large value of  $q$ , the electric field gradient at the nucleus. Furthermore, the ion must remain bound for a time long compared with  $\tau_c$ , while exchange with ions in the bulk solvent must occur in a time short compared with  $1/\pi\Delta\nu_b$ . The binding of chloride to mercuric ion appears to satisfy these requirements.<sup>5</sup>

It is possible to label specific sites in proteins with mercury, and thus use the chloride ion as a probe to examine these sites. Reaction of  $\text{HgCl}_2$  directly with SH groups on protein molecules can produce sites of the type P-S-Hg-Cl. In a typical experiment the chlorine nmr line width of a 0.5 M NaCl solution is 16 cps. Addition of  $1.4 \times 10^{-5}$  M hemoglobin causes the line to broaden slightly to 17 cps. When the solution is made  $2.8 \times 10^{-5}$  M in  $\text{HgCl}_2$ , the line width changes to 55 cps.

The effect of mercury on the chlorine line width in the presence of hemoglobin is very large. This is due to the long effective correlation time of  $^{35}\text{Cl}$  bound to the protein-mercury complex. If it is assumed that the mercuric ions react to completion with the two accessible SH groups, and that  $q$  has about the same value in P-S-Hg-Cl as in  $\text{HgCl}_4^{2-}$ , then the effective  $\tau_c$  for the Hg-hemoglobin site must be about 100 times as long as that for the small  $\text{HgCl}_4^{2-}$  complex. The correlation times observed in this work are frequently one or two orders of magnitude shorter than the time of rotation of the protein molecule as a whole.<sup>10</sup> In eq 1,  $\tau_c$  refers to the correlation time for the change in angle between the electric field gradient at the chlorine nucleus,  $q$ , and the external magnetic field,  $H_0$ . This angle is affected by motions within the protein-mercury complex as well as by rotations of the entire molecule. Hence the effective correlation times will be a com-

1. Titration of equine methemoglobin vs.  $\text{HgCl}_2$  at various concentrations. All solutions were adjusted to pH 7 with phosphate buffer: A,  $\text{NaCl} = 0.5 \text{ M}$ ,  $\text{Hb(E)} = 1.4 \times 10^{-5} \text{ M}$ ; B,  $\text{NaCl} = 2.0 \text{ M}$ ,  $\text{Hb(E)} = 7.0 \times 10^{-5} \text{ M}$ ; C,  $\text{NaCl} = 7.0 \times 10^{-5} \text{ M}$ ,  $\text{Hb(E)} = 7.0 \times 10^{-5} \text{ M}$ .

of these two factors. Thus  $\tau_c$  provides a measure of the rigidity of the structure at the cysteine site, as is the rotational correlation time of the entire molecule, and should be quite sensitive to any unfolding of the molecule.

#### Experimental Section

**Materials.** Twice-recrystallized horse methemoglobin, Hb(E), was obtained from Pentex, Inc. The human hemoglobin, Hb(A), was obtained from the Department of Biochemistry, Stanford Medical School. It was freshly prepared from normal adult human blood and stored in the cold. It was used in the oxy form, and was never kept for more than 1 week. All other chemicals were analytical reagent grade. When hemoglobin was dissolved in dissociating media, titration measurements were made on the same day. Some of the titrations were quite unstable; in these cases spectra were obtained within a few minutes after the solutions were prepared.

**Measurements.** The  $^{35}\text{Cl}$  spectra were obtained at 4.33 MHz using a Varian V-4311 fixed-frequency radiofrequency spectrometer. Base-line stabilization was achieved by field modulation and phase-sensitive detection using a PAR Model JB-4 lock-in amplifier. Calibration of the spectra was effected by the usual side-chain technique. All spectra were obtained at room temperature. Reported line widths are the average of at least five spectra, and in the case of very unstable samples where only the first few scans could be trusted.

8

experimental measurements are most conveniently carried out in the form of a titration. Hemo-

Figure 2. Titration of human oxyhemoglobin vs.  $\text{HgCl}_2$  at various  $\text{NaCl}$  concentrations. All solutions were adjusted to pH 7 with  $0.05 \text{ M}$  phosphate buffer: A,  $\text{NaCl} = 1.0 \text{ M}$ ,  $\text{Hb(A)} = 2.6 \times 10^{-5} \text{ M}$ ; B,  $\text{NaCl} = 4.0 \text{ M}$ ,  $\text{Hb(A)} = 5.1 \times 10^{-5} \text{ M}$ .

globin was dissolved in the selected medium containing  $0.5 \text{ M}$   $\text{NaCl}$ , enough  $\text{NaCl}$  so that the  $^{35}\text{Cl}$  resonance is readily observable. The nmr line width was followed as increasing amounts of  $\text{HgCl}_2$  were added. In the early stage of the titration, when reactive SH groups are present, each addition of  $\text{HgCl}_2$  causes the formation of P-S-Hg-Cl groups which results in a large increase in the  $^{35}\text{Cl}$  line width. When all the available SH groups have reacted, further addition of  $\text{HgCl}_2$  has little effect on the spectrum. A typical curve for horse methemoglobin is shown in Figure 1A. In this solution the dissociation of the protein is minimized by the low ionic strength and neutral pH. The end point at  $[\text{HgCl}_2]/[\text{Hb}] = 2$  is well defined showing that there are only two reactive SH groups per molecule. From eq 2 it is apparent that

$$\Delta\nu - \Delta\nu_a = K(M[\text{Hb}]/[\text{Cl}^-])(e^2qQ)^2\tau_c \quad (4)$$

where  $M$  is the number of  $\text{Cl}^-$  binding sites per labeled hemoglobin molecule,  $[\text{Hb}]$  is the concentration of labeled hemoglobin molecules, and  $[\text{Cl}^-]$  is the chloride ion concentration. If  $e^2qQ$  is assumed to be the same for all these solutions, then for given hemoglobin and chloride ion concentrations the slopes of the titration curves are simply proportional to  $\tau_c$ . It is known that hemoglobin will dissociate in solutions of high ionic strength.<sup>11</sup> At an  $\text{NaCl}$  concentration of  $4 \text{ M}$  the dissociation should be essentially complete. The titration curves in  $2.0$  and  $4.0 \text{ M}$   $\text{NaCl}$  are presented in Figures 1B and C, respectively. These curves clearly show that only two SH groups are reactive. The unreactive SH groups are not exposed to the solvent, even when the molecule is completely dissociated into halves. Similar curves for human oxyhemoglobin in  $1.0$  and  $4.0 \text{ M}$   $\text{NaCl}$  are shown in Figures 2A and B. The re-

(11) A. Rossi-Fanelli, E. Antonini, and A. Caputo, *J. Biol. Chem.*, **236**, 391 (1961).

Figure 3. Titration of equine and human hemoglobin vs.  $\text{HgCl}_2$  under acid conditions. All solutions were adjusted to pH 5.1 with 0.1 M acetate buffer: A,  $\text{NaCl} = 1.0 \text{ M}$ ,  $\text{Hb(E)} = 2.8 \times 10^{-5} \text{ M}$ ; B,  $\text{NaCl} = 2.0 \text{ M}$ ,  $\text{Hb(A)} = 2.6 \times 10^{-5} \text{ M}$ .

sults demonstrate that all but two of the SH groups are masked even in 4 M NaCl. Several of the titration curves show an anomaly at the point corresponding to  $[\text{HgCl}_2]/[\text{Hb}] = 1$ ; this solution shows less line broadening than expected. This is probably due to incomplete reaction between the  $\text{HgCl}_2$  and the active SH groups; the high chloride ion concentration may tend to hold a small fraction of the metal in the form of  $\text{HgCl}_4^{2-}$ .

The relative values of the effective correlation times calculated for these solutions are given in Table I. The correlation times measured by this method appear to increase under dissociating conditions. This behavior indicates that in the dissociated protein the motions of the  $^{35}\text{Cl}$  nucleus are more restricted than in the whole molecule. For a molecule of the size of hemoglobin, one would expect a rotational correlation time on the order of 100 nsec from the model of a sphere turning in a viscous liquid. Using eq 1 to calculate a value of  $\tau_c$  from this work we obtain an order of magnitude of 1 nsec, under the assumption that  $e^2qQ$  for the protein-Hg-Cl complex is the same as for solid  $\text{HgCl}_2$ . Hence  $\tau_c$  must be determined by motions faster than the rotation of the molecule as a whole, probably motions within the protein chains. Since  $\tau_c$  increases in dissociating media, it appears that dissociation into fragments may be accompanied by a

Table I. Relative Values of  $\tau_c$  for Hemoglobin

change in conformation of each fragment so as to restrict the motion of the bound chloride ions.

Since hemoglobin is known to dissociate in an acid medium,<sup>6</sup> a series of measurements was attempted on both the equine and human samples at a pH of 4.5. In this medium, protein denaturation occurred immediately after addition of the  $\text{HgCl}_2$ , and no meaningful data could be obtained. It is interesting however that the precipitation of the protein could be followed by a fall in the  $^{35}\text{Cl}$  line width with time. At a pH of 5.1 the denaturation was slowed to the point where the solutions were stable for a few minutes. By taking the spectrum immediately after the addition of  $\text{HgCl}_2$ , the curves shown in Figures 3A and B were obtained for equine and human hemoglobin at 1 and 2 M NaCl. Here again, only two active SH groups were found. Thus there is no difference in dissociation brought about by high ionic strength and that caused by a low pH insofar as events about the SH groups are concerned. Again the effective values of  $\tau_c$  appear to increase as shown in Table I.

The effect of urea on hemoglobin has been the subject of some confusion in the past. Steinhardt<sup>12</sup> showed that urea causes dissociation of equine CO-hemoglobin, whereas Gutter, *et al.*,<sup>13</sup> reported that human CO-hemoglobin is unfolded by urea without appreciable dissociation. Recently Kawahara, *et al.*,<sup>7</sup> showed that human CO-hemoglobin is indeed dissociated by urea, but they also reported a series of experiments indicating that simultaneous unfolding does not occur. Chlorine nmr titrations on both human and equine hemoglobin in 4 and 6 M urea solutions are shown in Figures 4 and 5. These results are quite different from the other titration curves. Although vestiges of the end points are evident for the titrations in 4 M urea, the results for 6 M urea show no sign of a break at  $[\text{HgCl}_2]/[\text{Hb}] = 2$ . Furthermore, for a given concentration of hemoglobin and  $\text{HgCl}_2$ , the line-broadening effect in the presence of urea and hence the effective  $\tau_c$  is less than is otherwise produced, as shown in Table I. This behavior cannot be due to an interaction of  $\text{HgCl}_2$  with urea; when the experiment is performed in the absence of hemoglobin, such effects are not observed. Urea seems to be unique in other respects as well. For ex-

Figure 4. Titration of equine methemoglobin vs.  $\text{HgCl}_2$  at various urea concentrations. All solutions were adjusted to pH 7 with 5 M phosphate buffer: A,  $\text{NaCl} = 1.0 \text{ M}$ ,  $\text{Hb(E)} = 2.8 \times 10^{-5} \text{ M}$ , urea = 4.0 M; B,  $\text{NaCl} = 1.0 \text{ M}$ ,  $\text{Hb(E)} = 2.8 \times 10^{-5} \text{ M}$ , urea = 6.0 M.

ample, the protein solutions were extremely stable in the presence of urea; no precipitation was ever observed in this medium. Unfortunately it was not possible to study solutions more concentrated in urea than 6 M, since at higher molarity of amide the solubility of  $\text{NaCl}$  was too low to obtain a good nmr signal.

## Discussion

The most interesting result of this work is the lack of activity of the unreactive SH groups even when the hemoglobin molecule is dissociated into halves. This indicates that the unreactive SH groups are incapable of forming structures of the type  $\text{P-S-Hg-Cl}$  which are exposed to the solvent. Such behavior could be due to any one of several causes. The mercuric chloride would react with the SH groups producing  $\text{P-S-Hg-S-P}$  linkages. These groups would probably produce no effect on the  $^{35}\text{Cl}$  nmr line width as shown by an earlier study of  $\text{Hg}(\text{SCH}_2\text{COOH})_2$ .<sup>5</sup> Such a result is unlikely, since the reactive SH groups do not form such bridges, it is improbable that the unreactive ones would. Another process consistent with the experimental data is the formation of  $\text{P-S-Hg-Cl}$  groups at the expense of the unreactive sulfhydryls, with the subsequent screening of these from the solvent by virtue of their location in inaccessible regions of the protein. A third possibility is that there is simply no reaction between  $\text{HgCl}_2$  and the unreactive SH groups. In either of the latter two cases, the inference is the same; the behavior of the unreactive SH groups is essentially unaffected by dissociation of the molecule. This result is consistent with the conclusion of Cecil and co-workers<sup>8,14</sup> that the unreactive SH groups are involved in intrachain binding and would be affected by an unfolding of the individual chains, but not by a simple dissociation of

Figure 5. Titration of human oxyhemoglobin vs.  $\text{HgCl}_2$  at various urea concentrations. All solutions were adjusted to pH 7 with 0.05 M phosphate buffer: A,  $\text{NaCl} = 1.0 \text{ M}$ ,  $\text{Hb(A)} = 2.6 \times 10^{-5} \text{ M}$ , urea = 4.0 M; B,  $\text{NaCl} = 1.0 \text{ M}$ ,  $\text{Hb(A)} = 2.6 \times 10^{-5} \text{ M}$ , urea = 6.0 M.

the hemoglobin molecule. This result is also consistent with the observation that the unreactive SH groups fail to react with iodoacetamide in 2 M  $\text{NaCl}$ .<sup>15</sup>

There appears to be no simple explanation for the behavior of the urea-hemoglobin systems. This is not surprising since these solutions contain two substances capable of affecting the protein. Urea solubilizes amide, peptide, and hydrophobic groups, while sodium chloride decreases the free energy of ionic groups in contact with the solvent. It is not clear what effect a combination of the two will have, but one would expect the mixture to be exceptionally active by analogy with guanidine hydrochloride which also contains an amide-like and an ionic component.

In complex systems it is not always possible to derive an unequivocal explanation of the experimental results from the nmr data alone. The line width depends on the product of two variables,  $P_b$  and  $\tau_c$ ; there is no simple way of separating the effect of each one. It is highly probable that the flexibility of the hemoglobin molecule is enhanced in urea solution, thus lowering  $\tau_c$ . The absence of an end point in the titrations in 6 M urea shows that  $P_b$  has also been affected. The absence of an end point even at mole ratios of  $[\text{HgCl}_2]/[\text{Hb}]$  in excess of six indicates that sites in addition to the sulfhydryl group for the formation of mercury complexes with the protein may be available in concentrated urea solutions or the equilibria involving the mercury atom are more complex. Speculation on the changes in gross structure, conformation, and chemical reactivity of hemoglobin in urea solution requires information such as molecular weights in addition to these nmr results.

## Communications to the Editor

## Rearrangement of the Allylcarbinyl Radical<sup>1</sup>

**Sir:**

Extensive carbon skeletal rearrangement accompanies the solvolyses of allylcarbinyl derivatives. These fascinating rearrangements have been the subject of a number of studies.<sup>2</sup> Vicinal vinyl group migrations occur with facility in allylcarbinylmagnesium halides and diphenylallylcarbinyl radicals.<sup>3</sup> In this communication we wish to report two types of intramolecular structural transformations that allylcarbinyl radicals undergo, as well as several observations which are germane to the detailed mechanism of these changes.

In preliminary experiments it was determined that 4-pentenal decarbonylates by way of a radical chain process (di-*t*-butyl peroxide, chlorobenzene, 130°), yielding 1-butene as the virtually exclusive hydrocarbon product. In order to seek out conceivable carbonyl skeletal rearrangements that might take place during this reaction, the decarbonylation products of 4-pentenal-2,2-*d*<sub>2</sub> were examined. A 1.0 *M* solution of 4-pentenal-2,2-*d*<sub>2</sub> afforded 1-butene-4,4-*d*<sub>2</sub> and 1-butene-3,3-*d*<sub>2</sub> in roughly equal quantities (mass spectral analysis). Recovered, unreacted 4-pentenal-2,2-*d*<sub>2</sub> was not rearranged. Following a procedure developed previously in studies of the decarbonylations of 2- and 3-methyl-4-pentenals and 2- and 3-methyl-*trans*-4-hexenals<sup>4</sup> which facilitates quantitative interpretation of the rearrangement data, a series of 4-pentenal-2,2-*d*<sub>2</sub> solutions, varying in concentration from 0.50 to 6.0 *M*, was prepared and allowed to react to only a few per cent conversion. 1-Butene-4,4-*d*<sub>2</sub>:1-butene-3,3-*d*<sub>2</sub> ratios were determined for each solution. Ratios for the 0.50–1.5 *M* solutions were all close to 1.0:1.0. There was, however, a small but clearly discernible monotonic increase in the ratios (10–20%) in going from the solutions in the concentration range 0.50–1.5 *M* to the 6.0 *M* solution.<sup>5</sup> The magnitude of this increase is in reasonable agreement with that which would be pre-

dicted from the decarbonylation studies on 2-methyl- and 3-methyl-4-pentenals.<sup>4a</sup> The variation in ratios demonstrates that a *minimum* of two radical intermediates gives rise to the observed olefinic products. Classical<sup>4a,6</sup> radicals 1 and 2, which are interconvertible by vicinal vinyl group migration, suffice nicely as the required intermediates. Homoallylic radicals 1 and

2 must interconvert moderately fast to be compatible with the data. In terms of the proposed mechanistic scheme, the decrease in the extent of rearrangement with increasing aldehyde concentration results from increased trapping of 1, which is formed initially from 4-pentenal-2,2-*d*.

If the interconversion of 1 and 2 is intramolecular, a reasonable assumption, a half-migrated entity of cyclopropylcarbinyl structure must be implicated in the very least as a transition state in the rearrangement sequence. The question arises as to whether a cyclopropylcarbinyl intermediate is also involved. In an effort to probe this point, *cis*-4-pentenal-5- $d_1$  (95% *cis* as inferred by proton nmr analysis) was synthesized and its decarbonylation products were examined. Radical chain decomposition of *cis*-4-pentenal-5- $d_1$  should generate homoallylic radical 3 initially. If half-migrated structure 4 is merely a transition state for carbon skeletal rearrangement, bond a should be formed

and bond b broken without a loss of geometrical identity about bond c, for transition-state lifetimes are generally considered to be short<sup>7</sup> relative to internal rotational lifetimes.<sup>6</sup> Decarbonylation of a 1.0 *M* solution of *cis*-4-pentenal-5-*d*<sub>1</sub> gave *cis*-1-butene-1-*d*<sub>1</sub> and *trans*-1-butene-1-*d*<sub>1</sub> in a 1.03:1.00 ratio (nmr). Recovered starting material had not rearranged. A straightforward explanation of these results is that a cyclopropylcarbinyl radical like **4** is a reaction intermediate and that the double bond geometry of the starting aldehyde is lost in intermediate **4** through rotation

Figure 1. Distribution of the deuterium label as inferred by nmr spectroscopy in products from the decomposition of deuterium-labeled *t*-butyl ( $\gamma,\gamma$ -diphenylallyl)peracetate in (a) cyclohexane at 125°, and (b) 1.34 *M* triethyltin hydride in *n*-octane at 125°.

actually VII or a tetrahydronaphthalene believed to correspond to an as yet uncharacterized reaction product.

A detailed product analysis to be reported later indicates that relative yields of diphenylcyclopropylmethane and diphenylbutene formed from either perester in 1,4-cyclohexadiene as a function of initial perester and cyclohexadiene concentrations are compatible with VI being formed mainly through donation of hydrogen to II by cyclohexadienyl radicals while V arises similarly from I and 1,4-cyclohexadiene. In the solvents which are poor hydrogen donors, VI can be formed by hydrogen abstraction from VIII.<sup>9</sup>

For the decomposition of III in triethyltin hydride-*n*-octane mixtures, the ratio VI:V is independent of the tin hydride concentration. This observation indicates that the rearrangement of I to II is fast with respect to hydrogen abstraction by I from the hydride, or that there is a single "nonclassical" radical of intermediate structure which gives rise to both hydrocarbons. Thus, the degree of equivalence attained by the methylene groups in I before conversion to product is of special interest. To determine this, perester III was prepared with 1.40 g-atoms of deuterium in the  $\alpha$  position. Following decomposition in cyclohexane at 125°, the distribution of the deuterium label in VII, the major reaction product, was determined by nmr spectroscopy. The results are summarized in Figure 1a.

It is clear that the rearrangement of I to II must be fast with respect to that of I to VIII. Here, the time during which the rearrangement may take place is limited only by the relatively slow rate at which the *ortho* ring cyclization occurs. Decomposition of III in the presence of 1.34 *M* triethyltin hydride made it possible to reduce this time by approximately a factor of 23, according to the value of  $k_a/k_r$  estimated for the tin hydride. Nonetheless, nmr analysis of the 1,1-diphenyl-1-butene (V) formed showed equilibration of

(9) The major difference in the amount of VI formed in the decomposition of the two peresters in cyclohexadiene (see Table I) can be understood essentially as follows. The half-life for decomposition of ring-opened perester, III, at 131° is about the same as that for IV at 35°. The steady-state cyclohexadienyl radical concentration goes roughly as the square root of the decomposition rate. Therefore, the cyclohexadienyl radical concentration will be about the same in the two cases. However, the steady-state concentration of the ring-closed radical, II, will be quite different. If, as we believe, II is energetically more stable than I, the ratio I:II will be greater at the higher temperature. The rates of hydrogen abstraction to give V and of conversion to ring-cyclized radical VIII will then be much faster at 131° due both to the temperature effect on  $k_a$  and on  $k_r$  and to the greater relative amount of I. As a result, the steady-state concentration of II will be much smaller at 131° than at 35°, and the amount of VI formed will be correspondingly less.

the methylene groups to have occurred even in the presence of this active hydrogen donor (Figure 1b). Thus, the half-time for the isomerization of I to II must be short compared to that for the reaction of the former with the tin hydride.

At present there is no reason to postulate the existence of a "nonclassical" radical species to account for the experimental results and, on the whole, the radical system behaves more like the analogous carbanion system<sup>3</sup> than like similar carbonium ion systems.<sup>4</sup> Possible answers to the intriguing question<sup>10</sup> as to the magnitude of the equilibrium constant between I and II will be considered in detail later.

### pH-Dependent Proton Absorption in Chymotrypsin Binding. Evidence for a pH-Dependent Conformation Change of the Enzyme<sup>1</sup>

Sir:

The second-order rate constant ( $k_{cat}/K_m(\text{app})$ ) of chymotrypsin-catalyzed reactions has long been known to decrease above pH 8, with an apparent dependence on a single ionizable group of  $pK \sim 9$ .<sup>2</sup> Recently this phenomenon has been identified as a pH-dependent binding by chymotrypsin, even for neutral substrates and inhibitors.<sup>3-5</sup> A pH-dependent binding of a neutral molecule implies that a pH-dependent proton change of the enzyme occurs on binding. In fact, a pH-dependent absorption of one proton per mole of enzyme has been observed upon acylation of chymotrypsin.<sup>7</sup> Is this proton phenomenon at high pH associated with the noncovalent binding of substrate to enzyme ( $K_d$ ) or with the subsequent covalent acylation step ( $k_2$ )? Recent results with competitive inhibitors of chymotrypsin<sup>4</sup> and with derivatized chymotrypsins<sup>8</sup> favor the former possibility.

The binding of the competitive inhibitor, benzyl alcohol, to  $\alpha$ -chymotrypsin was first investigated. This substance is particularly advantageous since it is endowed with both high solubility and partial resemblance to a natural chymotrypsin substrate; solutions with  $[I]_0/K_i = 20$  can easily be prepared, leading to essentially complete saturation of the enzyme by the inhibitor even at high pH. The results of a series of experiments determining proton uptake by the enzyme upon binding of excess benzyl alcohol are shown in

re 1. At pH 7, no protons are absorbed by the enzyme on binding while at pH's near 10 almost one proton per mole of enzyme is absorbed. The pH dependence of the proton uptake follows a sigmoidal curve (solid line) based on a single  $pK$  of 8.8, similar to the  $pK$  controlling the pH-dependent binding of the enzyme in this region.<sup>4</sup> Thus, the shapes of the  $1/K_i$  (or  $1/K_s$ ) vs. pH curves and the proton uptake vs. pH curves are essentially identical with one another. Likewise, plots of proton absorption vs. inhibitor concentration show saturation curves similar to normal ( $V$  vs.  $[S]$ ) saturation binding curves. The results are obtained with acetonitrile, a nonspecific inhibitor, and N-acetyl-D-tryptophanamide, a specific inhibitor.

At pH 8.8 the addition of benzyl alcohol ( $[BzOH] \gg 0.5$  proton per mole of enzyme to be absorbed, and the further addition of acetonitrile, also in increasing concentration, caused no further changes in the state of protonation of the enzyme. Thus the effect of added inhibitor, especially acetonitrile, is due to a specific enzyme-small molecule interaction and not to altered solution properties.

These results suggest that the proton uptake seen in the overall acylation ( $k_2/K_2$ ) actually occurs in the binding step ( $K_2$ ) preceding acylation ( $k_2$ ). In the acylation step *per se* no further proton uptake can occur, so it is all accounted for in the binding.

These results further indicate that a set of coupled equilibria involving binding and protonation of the enzyme must occur. A set of coupled equilibria was previously used to explain the pH-dependent binding and proton release on binding of oxygen to hemoglobin, the so-called Bohr effect.<sup>9,10</sup> The simplest expression of coupling in the chymotrypsin system is

implying that  $EH^+$ , but not  $E$ , can bind inhibitor (or rate) and that  $EH^+$ , but not  $EHI^+$  ( $EHS^+$ ), can lose a proton. This set of equations, related to the hemoglobin equations,<sup>9</sup> successfully describes the sigmoidal shape of Figure 1 and the corresponding sigmoidal shape of  $1/K_i$  vs. pH. However, eq 1 suffers from two faults: (1) it gives no mechanistic explanation for the binding of a neutral inhibitor to a protonated enzyme, but not to a neutral enzyme,  $E$ ; and (2) it does not account for the change in state of the enzyme seen symmetrically around pH 9.<sup>11</sup> In order to meet these requirements, eq 1 has been expanded to eq 2.

The scheme, which postulates two states of the enzyme, equalizes the pH dependence of both binding and proton uptake. Provided that  $K_{TH} (= [EH]/[E^*H]) \geq 1$  and that  $[H^+] \gg K_a \leq 10^{-11}$ ,<sup>12,13</sup> sigmoidal pH

Figure 1. The pH dependence of proton absorption by  $\alpha$ -chymotrypsin upon binding of inhibitors: O, benzyl alcohol (pH 7.9:  $K_i = 10$  mM, competitive inhibition; 10 mM, proton absorption; pH 9.0:  $K_i = 17$  mM, competitive inhibition; 21 mM, proton absorption; pH 9.7:  $K_i = 50$  mM, competitive inhibition; 51 mM, proton absorption);  $\Delta$ , acetonitrile ( $K_i = 830$  mM, pH 7.9);  $\square$ , N-acetyl-D-tryptophanamide ( $K_i = 2.3$  mM, pH 7.9).  $[E]_0 = 0.86 \times 10^{-4}$  M;  $[I]_0$  always  $5 \times > K_{i, \text{obsd}}$  at each pH; 25.0°, 0.1 M KCl. Observations of proton absorption by  $\alpha$ -chymotrypsin were made using a recording pH meter: ordinary glass and calomel electrodes in a Faraday cage with a Radiometer TTTic pH-Stat regulator unit used to drive a Sargent SR recorder, for which full scale could be varied from 1.0 to 0.01 pH unit. Inhibitor was added with a Gilson micrometer buret *via* a Teflon needle. Chymotrypsinogen was used as a "blank" reaction to correct for small (0–25%) pH changes due only to addition of inhibitor. The value of the pH change on addition of inhibitor to  $\alpha$ -chymotrypsin was compared to that produced artificially by addition of 1 equiv of hydroxide ion/mole of enzyme to obtain the fraction of one proton absorbed by the enzyme per mole at the given pH.  $\Delta pH$  values from 0.05 to 0.16 were observed.

dependence of both processes is predicted. Thus  $E$  is the major form of the enzyme when protonated, and  $E^*$  is the major form when unprotonated.

The symbol  $n$  is defined as the number of protons per mole of enzyme which are released as the result of forming the enzyme-inhibitor complex (*cf.* ref 7 for a similar definition). Using the scheme of eq 2, one may then derive eq 3 and 4. Equation 4 predicts that a plot

$$\frac{1}{K_{i, \text{obsd}}} = \frac{(1/K_i)}{\left(1 + \frac{K_a}{K_T[H^+]}\right)} \quad (3)$$

$$n = \frac{1}{\left(1 + \frac{K_a}{K_T[H^+]}\right)} - \frac{\left(1 + \frac{[I]}{K_i}\right)}{\left(1 + \frac{K_a}{K_T[H^+]} + \frac{[I]}{K_i}\right)} \quad (4)$$

of  $n$  vs.  $[I]$  at a given pH will produce the usual hyperbolic saturation curve (as seen for  $V$  vs.  $[S]$ ), leading to the same  $K_{i, \text{obsd}}$  as that obtained by competitive inhibition experiments. Indeed this is observed and proven in experiments carried out at pH 7.8, 8.8, and 9.6.

The dissociation constants of these species are infinite. Havsteen<sup>11</sup> has produced kinetic evidence for the top of the cube ( $E^*H^+$ ,  $EH^+$ ,  $EHI^+$ , and  $E^*HI^+$ ) by observing at high pH one relaxation of the enzyme itself, and two relaxations of the enzyme in the presence of the inhibitor proflavin. We find that proflavin is a special case: its binding is decreased only twofold at pH 10 where the binding of many other inhibitors is decreased *ca.* tenfold, implying that proflavin can bind not only at the active site where the change of state occurs, but possibly at some second site also.

J. Wyman, *Advan. Protein Chem.*, **4**, 407 (1948).

R. A. Alberty, *J. Am. Chem. Soc.*, **77**, 4522 (1955).

B. H. Havsteen, *J. Biol. Chem.*, **242**, 769 (1967).

The assumption that  $K_{TH} \geq 100$  is borne out by the data on the titration of the enzyme alone.<sup>11</sup>

Equation 2 represents two sides of a cubic array. The other sides of the cube,  $E^*HI^+$  and  $E^*I$ , have been omitted, implying that

The change in state between E and E\* in the native enzyme may be described as a change in hydration or, more probably, a conformational change of the native enzyme. Although the binding and proton absorption data require that E be the major form when protonated and E\* be the major form when unprotonated, the introduction of inhibitor (or substrate) into the system transforms all of the enzyme to EHI<sup>+</sup> (or EHS<sup>+</sup>), which explains the pH-independent catalytic steps ( $k_2$  and  $k_3$ ) in the high pH region. The conformational change thus is related to the binding of small molecules at the enzyme active site but not to the catalytic process *per se*. A pH-dependent intramolecular competitive inhibition of the active site will explain the data on the transformation given both here and elsewhere.<sup>4</sup> Although this (conformational) change drastically affects the activity of chymotrypsin through an inhibition of binding, it does so only in a negative way.

## On the Mechanism of Aromatic Arylation with Nitrosoacetanilide

Sir:

Nitrosoacetanilide (1) has long been known as a source of phenyl radicals<sup>1</sup> and has found particular application in studies of homolytic phenylation of aromatic compounds.<sup>2,3</sup> It has been established that the rate-determining step in these reactions is the first-order isomerization (eq 1) leading to benzene-diazo acetate.<sup>4</sup> However, the detail of subsequent processes has been less clear. Two major difficulties challenged early mechanistic ideas. First, early schemes show the high yields of acetic acid arising by way of the acetyloxy radical, in spite of the known instability of this intermediate.<sup>5</sup> Second, the initial adduct of phenyl radicals to benzene (*i.e.*, the phenyl-cyclohexadienyl radical, 2) is cleanly oxidized to biphenyl, while in other systems disproportionation and dimerization lead, in addition, to hydroaromatic products.<sup>6</sup>

The difficulties referred to have led to suggestions of concerted<sup>4,7</sup> or cage<sup>8</sup> processes. However, a more satisfactory mechanistic interpretation, which has received general acclaim,<sup>9</sup> was advanced recently by

Rüchardt and his collaborators<sup>10</sup> and was successfully extended to the Gomberg reaction.<sup>11</sup> In this new scheme, outlined below for the phenylation of benzene, the acetic acid is formed in a nonradical process involving the ion-pair form<sup>12</sup> of the diazoacetate. Furthermore, rapid oxidation of radical 2 by a high stationary-state concentration of the phenyldiazotate radical

Initiation

Major product-forming sequence

(PhN=NO·) accounts for the failure to observe disproportionation or dimerization products from 2. This mechanism received added support when a stable radical was detected in the reaction by electron spin resonance (esr),<sup>13</sup> and its spectrum was interpreted in terms of the phenyldiazotate structure ( $a_N = 1.67$ , 11.61;  $a_H = o$ -, -2.60;  $m$ -, 0.89;  $p$ -, -2.73). The larger nitrogen splitting has subsequently been assigned to the nitrogen atom bonded to oxygen, by means of <sup>15</sup>N labeling experiments.<sup>14</sup>

Our interest<sup>15</sup> in the scavenging of phenyl radicals by C-nitroso compounds (to give nitroxide radicals) led us to propose that the radical detected by Rüchardt and Binsch<sup>13</sup> might, in fact, have structure 3. Any hyperfine splitting by the protons in ring B may have been too small to have been resolved.

We have redetermined the esr spectrum of the stable radical from the decomposition of nitrosoacetanilide in benzene (Figure 1) and have now been able to obtain

p 154. A related mechanism has been advanced, with little supporting evidence, for homolytic phenylation by N-phenyl-N'-tosyloxydiimide N-oxide: E. A. Dorko and T. E. Stevens, *Chem. Commun.*, 871 (1966).

essentially the same spectrum by mixing benzene solutions of nitrosobenzene and *N*-bromoacetanilide (Figure 2). We consider that the most probable structure for the radical responsible for this spectrum is therefore 3; in the second reaction this is considered to arise by addition of the nitrogen-centered radical 4 to nitrosobenzene (eq 9).<sup>16</sup> The <sup>15</sup>N experiments already cited<sup>14</sup> once more allow assignment of the larger nitrogen coupling in radical 3 to the nitrogen atom bonded to oxygen. The value of 11.7 gauss seems very reason-

able for nitrogen in this environment, by analogy with other data on nitroxide radicals.<sup>17</sup>

Reaction of *N*-bromo-*p*-chloroacetanilide with nitrosobenzene gives a radical whose esr spectrum is indistinguishable from that of 3, consistent with the hypothesis of negligible splitting by the ring B protons. Reactions of *N*-bromoacetanilide with *p*-chloronitrosobenzene, *p*-nitrosotoluene, and 2-methyl-2-nitrosopropane also give stable radical species, the esr spectra of which have been resolved into 50, 42, and 9 lines, respectively.<sup>18</sup> These reactions appear to constitute the first examples of addition of organic nitrogen-centered radicals to the nitroso group, though there are now numerous reports of additions by carbon-<sup>19</sup> and oxygen-centered<sup>20</sup> radicals.

Assuming that structure 3 correctly represents the structure of the stable radical in the nitrosoacetanilide reaction, this species could then adopt the role of oxidant in a modified mechanism such as that outlined below. This finds close analogy with the mechanism proposed for the decomposition of benzoyl peroxide in the presence of diphenyl nitroxide.<sup>18</sup>

#### Initiation

(16) The esr spectrum developed on mixing the reagents, though photolysis of the bromo amide by stray laboratory light may have been instrumental in radical production. At room temperature, the presence of silver powder did not increase the radical concentration. In a control experiment, no radical spectrum was formed from nitrosobenzene and molecular bromine. Spectra were recorded on a modified Varian V4502 spectrometer generously placed at our disposal by Dr. G. R. Wilkinson of the Physics Department of this college. We are also indebted to Dr. Yvonne Rees for a helpful appraisal of various sources of phenylacetamido radicals.

(17) For example, compound i has  $a_N = 16.2$  gauss in methylene chloride: J. W. Lown, *J. Chem. Soc., Sect. B*, 441 (1966). This value might be expected to be reduced slightly in 3 by delocalization of the unpaired electron over the aromatic ring (cf. ref 18).

(18) The last of these (nine lines) appeared as a triplet of triplets ( $a_H = ca. 16$  and 1.5 gauss) and is ascribed to *t*-BuN(O)N(Ph)COCH<sub>3</sub>. This radical has not yet been obtained free from di-*t*-butyl nitroxide, despite attempts to avoid direct photolysis of the nitrosobutane (see ref 19). The spectrum in Figure 1 has been analyzed in detail<sup>15,16</sup> and involves considerable coincidence of lines. There must also be coincidences in the spectra of the chloro- and methyl-substituted radicals and analysis of the spectra of these and related nitroxides will be given in the full paper.

Figure 2. Esr spectrum of the radical formed on mixing benzene solutions of *N*-bromoacetanilide and nitrosobenzene.

#### Main product-forming sequence

Reaction 12 may represent more than one discrete step. The reduced yield of biphenyl with high initial concentrations of nitrosoamide might be explained in terms of increased removal of phenyl radicals in reaction 8, leading to unidentified by-products.

Other examples of phenylation reactions in which product formation is dominated by the presence of relatively stable radical intermediates have also been documented.<sup>21</sup> In the light of the present work, the identity of any such species in the Gomberg reaction<sup>11</sup> merits reinvestigation.

#### A New Versatile Ketone Spin Label

Sir:

The study of molecular systems by esr spectroscopy is contingent on the presence within the system of un-

Table I. Physical and Spectral Data

Nitroxide	Mp or bp (mm), °C	$a_N^a \pm 0.1$ gauss	$g$ value, $\pm 0.0002$	$\lambda_{max}$ , m $\mu$ ( $\epsilon$ )	% yield
	175-176 (methanol- ether)	14.3	2.0058	443 (7.2) (ether)	70 <sup>b</sup>
	57-58 (pen- tane)	14.3	2.0058	420 (7.4) (ethanol)	42 <sup>c</sup>
	~70 (0.08)	14.4	2.0058	422 (7.0) (ethanol)	26 <sup>d</sup>

<sup>a</sup> X-band esr spectra were measured in ethyl acetate solution ( $ca. 5 \times 10^{-4} M$ ) and consisted of the usual three-line nitroxide spectra. All three nitroxides were found to have  $1.0 \pm 0.2$  spins per molecule. <sup>b</sup> This represents pure crystalline material. <sup>c</sup> Yields were determined by visible absorption spectroscopy. <sup>d</sup> The analytical specimen was obtained by preparative vapor phase chromatography.

paired electron spins. Elegant methods have recently been developed for the chemical attachment of relatively stable nitroxide free radicals to diamagnetic biomolecules, permitting study of the latter by esr techniques. Several workers have applied this spin-labeling method with notable success to the study of proteins such as bovine serum albumin.<sup>1</sup>

The continuing successful development of this technique depends to a large measure on the availability of a wide variety of spin-label molecules. We wish to report the first general method for converting ketones to stable nitroxide free radicals. The reaction sequence from the ketone to the nitroxide is outlined below.

For example, refluxing a toluene solution of cholestan-3-one containing an excess of 2-amino-2-methylpropan-1-ol<sup>2</sup> and a trace of *p*-toluenesulfonic acid monohydrate for several hours with continuous water removal by means of a Dean-Stark trap led to the corresponding oxazolidine, one epimer of which had mp 124-125°. The known<sup>4</sup> oxazolidines derived from cyclohexanone and heptan-2-one were similarly prepared.

In each instance oxidation of the oxazolidine to the corresponding nitroxide was effected by dropwise addition over 20 min of an ether solution of 1.50 equiv of *m*-chloroperbenzoic acid to an ice-cold, stirred ether

solution of oxazolidine. The resulting solution was allowed to stand at 25° for 24 hr. The ether layer was washed with cold 5% sodium bicarbonate solution and dried over magnesium sulfate, and the solvent was removed under vacuum, affording the nitroxide. Table I summarizes pertinent physical and spectral data for the three representative nitroxides 1, 2, and 3.

The conformationally rather rigid nature of the oxazolidine ring system in these new spin labels should markedly facilitate the interpretation of rotational correlation times in terms of the local environment of the spin label.

### Concerning the Anion and Cation Radicals of Corannulene

Sir:

The consideration of valence bond structures such as 2 for the recently synthesized strained, nonalternate benzoid hydrocarbon, corannulene (1),<sup>1</sup> intimated the theoretical accessibility of the corresponding radical anion and radical cation derivatives. The unusual polar form 2 implies that the radical cation and anion correspondingly will have large contributions of structures such as 3 and 4 to the resonance hybrid. Because of the importance of these species to more sophisticated computations on the corannulene molecule, as

(1) W. E. Barth and R. G. Lawton, *J. Am. Chem. Soc.*, **88**, 380 (1966).

general interest in its chemistry, we were to search for these derivatives.

graphic reduction of  $1 \times 10^{-3} M$  corannulene-nutylammonium perchlorate solution in acetone using either a stationary platinum microelectrode or a dropping mercury electrode afforded two well-resolved waves with half-wave potentials,  $E_{1/2}$ , of  $-2.36$  v vs. the Ag-AgCl aqueous reference electrode. That the first wave on both electrodes indicated a reversible, one-electron reduction was confirmed by wave log analysis and controlled potential electrolysis. The corannulene radical anion product of the first reduction wave was characterized by spectroscopic and esr techniques in the following.

Controlled potential electrolysis on a macroreticulated mercury pool electrode and at a potential of  $-2.5$  v using a specially constructed flow cell<sup>2</sup> which was mounted in a Cary Model 14 spectrophotometer in the formation of a dark emerald green solution having maxima in the visible at 450 and 650 m $\mu$  (Figure 1A, curve 1). However, the ratio of intensities of the peaks at 450 and 650 m $\mu$  varied over a range of more than a single species. Upon exposure to oxygen the green solution became yellow and its visible spectrum exhibited a single peak at 450 m $\mu$ . Thus, it is believed, the green color is a result of the summation of the radical anion at 650-m $\mu$  maximum and a decay product 450-m $\mu$  maximum caused by trace amounts of oxygen in solution.

Dark green solutions were observed upon reduction of  $1 \times 10^{-4} M$  solutions of corannulene in tetrahydrofuran by potassium or sodium metal. At room temperature these solutions exhibited esr spectra consisting of 11 equally spaced lines (Figure 1B), the clearest being observed only under conditions of high gain and resolution. The spectrum and its intensity distribution is exactly that expected for a radical with one set of ten equivalent protons. Confirmation that the chemically and electrolytically prepared species were identical was obtained by electroreduction in the esr cavity of a  $10^{-3} M$  solution of corannulene in dimethylformamide at a potential of  $-2.5$  v vs. a Ag-AgCl reference electrode, giving an identical esr spectrum with that obtained chemically. The hyperfine splitting constant for the radical anion in dimethoxyethane was  $a_H = 1.560 \pm 0.005$  gauss,

data and H. B. Mark, Jr., to be published.

Figure 1. (A) Visible spectrum of electrolysis products produced at  $-2.0$  (curve 1) and  $-2.5$  v (curve 2) vs. a Ag-AgCl reference electrode. (B) ESR spectrum of corannulene anion radical.

and the  $g$  value was  $2.00270 \pm 0.00001$ . The splitting constant in dimethylformamide is identical within experimental error.

Controlled potential electrolysis at  $-2.5$  v vs. Ag-AgCl (diffusion plateau of second wave) produced a bright red species having a single absorbance maximum at 500 m $\mu$ . This same red substance could also be observed when corannulene solutions were subjected to long contact with alkali metals. The red species, which is not paramagnetic, is not believed to be the dianion, but rather some decay product of it. Further studies of this reaction are in progress.

Attempts to observe the radical cation (4) were uniformly unsuccessful; using a slow anodic sweep of a platinum electrode, a poorly defined oxidation wave was obtained with a half-wave potential of about  $1.46$  v vs. Ag-AgCl. The wave is actually peaked in shape. Apparently the oxidation product of corannulene undergoes rapid chemical reaction, producing a polymeric product which coats the electrode surface and blocks further oxidation. The passivation prevented any anodic coulometric study. Further, an attempt to observe an esr signal under similar conditions was also unsuccessful.

The neutral corannulene molecule is highly strained, and one would not expect it to be planar. A possible bowl-shaped configuration which preserves the five-fold symmetry of the planar structure was suggested by Barth and Lawton.<sup>1</sup> If the simple Hückel method is used to treat the  $\pi$  system, one possible model in which deviations from planarity can be approximately treated is by a reduction in the  $\beta_{ij}$  for the five bonds between the inner and outer rings. The difference in  $\pi$  energy between planar and nonplanar forms for the radical is less than this difference for the neutral molecule. This indicates that no added stability for the planar configuration is obtained on going from the neutral species to the radical anion and hence, if the neutral molecule is nonplanar, the anion radical is likely to be also.<sup>3</sup>

A bowl-shaped configuration for the anion radical is consistent with the esr observation of ten equivalent protons. In any structure maintaining fivefold sym-

(3) Dr. Gerald J. Gleicher has carried out extensive SCFMO strain calculations, which are to be published.

metry, the unpaired electron occupies a degenerate orbital. Averaging over the ten hydrogen-bonded positions one can obtain average Hückel spin densities,  $\langle \zeta \rangle$ , and excess charge densities  $\langle \epsilon \rangle$ . For the radical anion,  $\langle \zeta \rangle$  is 0.0630 in the planar configuration ( $\beta_{10} = 1.00$ ), decreases slightly to a minimum value of 0.0616 for  $\beta_{10} = 0.72$ , and is 0.0667 for  $\beta_{10}$  zero.

For corannulene, one is not sure of the  $\sigma$  framework for the carbon atoms with bonded hydrogen, but if we use the McConnell and Colpa-Bolton relationships,  $a^M = 27\zeta$  and  $a^{CB} = -27\zeta + 12.8\epsilon$ , as discussed by Snyder and Amos,<sup>4</sup> we find for the planar configuration  $a^M = -1.70$  and  $a^{CB} = -1.66$ ; if  $\beta_{10} = 0.72$ ,  $a^M = -1.66$  and  $a^{CB} = -1.63$ . The calculation for the nonplanar configuration including the excess charge effect gives the best agreement with the experimental value  $|a| = 1.56$ . The agreement between the calculated and experimental values is somewhat surprising considering the nature of the approximations that have been made. However, in the case of coronene anion radical, which is alternate and planar, the calculated splitting using average Hückel spin and charge densities is  $-1.49$ , compared with an experimental value of  $-1.47$ .<sup>5</sup>

Segal, *et al.*,<sup>6</sup> have found, in agreement with Stone's theory,<sup>7</sup> that the  $g$  values of hydrocarbon radicals can be fitted very well by  $\Delta g = g - g_0 = (31.9 - 16.6\lambda) \times 10^{-5}$ . Here  $g_0$  is the free-electron value and  $\lambda$  is the Hückel energy level coefficient of the unpaired electron orbital. Segal found that the  $g$  value of radicals such as coronene with the unpaired electron in a degenerate orbital do not conform to this relationship, but corannulene does. For corannulene the experimental value of  $\Delta g$  is  $38 \times 10^{-5}$  and the calculated values for planar ( $\beta_{10} = 1.00$ ) and nonplanar ( $\beta_{10} = 0.72$ ) are  $40 \times 10^{-5}$  and  $38 \times 10^{-5}$ , respectively.

## On the Dissociation and Reassociation of the Polypeptide Chains of Tropomyosin and Paramyosin<sup>1</sup>

Sir:

The molecules of tropomyosin and paramyosin are similar. In benign media, both consist of two  $\alpha$ -helices arranged side by side and twisted slightly about one another.<sup>2-4</sup> Thus, although they differ significantly in amino acid composition, the only gross difference in molecular form is in the over-all molecular length.

(3) A. Holtzer, R. Clark, and S. Lowey, *Biochemistry*, **4**, 2401 (1965).

(4) C. Cohen and K. C. Holmes, *J. Mol. Biol.*, **6**, 423 (1963).

Further questions immediately arise. Among these are: (1) How many individual polypeptide chains make up each molecule? Is there one long chain with a hairpin turn between long helical segments, or two completely helical chains held side by side, etc.? (2) Are there any covalent cross-linkages (in particular, disulfide bonds) between the two helical segments? (3) Are the covalent cross-linkages, if any, necessary to maintain the native conformation?

Two of these questions have already been answered for tropomyosin.<sup>4,5</sup> We report here experimental results which answer all three for both proteins. Except where otherwise noted, preparative methods and physical techniques were as reported earlier.<sup>2,3</sup>

**Tropomyosin.** A molecule of tropomyosin has a mass of 74,000 amu.<sup>3</sup> In a denaturing medium in which the helix content (measured by optical rotatory dispersion) is zero, the same mass is observed, and the other solution properties are not those of a linear, random coil of that mass.<sup>3</sup> Clearly, then, this molecule has one or more covalent cross-linkages. This agrees with chemical studies, which indicate one disulfide bond/molecule.<sup>6</sup> In a medium that would reduce disulfide linkages, the molecular mass is about one-half the value given above.<sup>5</sup> Thus, there are two polypeptide chains in tropomyosin, as it is usually prepared, held together by at least one disulfide linkage.

To investigate further, we prepared tropomyosin samples that had all the disulfide linkages reduced to sulfhydryl, and then all sulfhydryls were masked with acetyl groups. This was accomplished by dissolution of native tropomyosin in a denaturing medium (5 *M* guanidine hydrochloride), reduction with  $\beta$ -mercaptoethanol, acetylation with iodoacetic acid, dialysis, and lyophilization. This lyophilized material ("modified" tropomyosin) was dissolved in both benign and denaturing aqueous media, and several macromolecular properties of these solutions were determined. Specifically, measurements were made of intrinsic viscosity, intrinsic sedimentation coefficient, and (light scattering) molecular weight. In parallel, measurements of intrinsic viscosity and sedimentation coefficient were made on solutions of unmodified tropomyosin. Results for both kinds of material are summarized in Table I (rows labeled TM).

The data in Table I confirm our earlier experiments on unmodified tropomyosin in both media. We have also confirmed that the molecular weight of unmodified tropomyosin, in a medium that is both reducing and denaturing, is one-half that value. It is also plain from the table that the properties of modified and unmodified tropomyosin are quite different from one another in the denaturing medium, but are indistinguishable in the benign medium.

Most striking is the drop in molecular weight (by a factor of two) suffered by the modified protein when transferred from the benign to the denaturing medium and its complete recovery upon transfer back to the benign medium.

**Paramyosin.** A paramyosin molecule has a mass of 220,000 amu.<sup>2</sup> The molecule is extraordinarily stable; optical rotatory dispersion experiments show appreci-

Mandelkern, *ibid.*, 75,

content, at 25°, up to a guanidine concentration of 7.0 M.<sup>7,8</sup> Chemical studies have revealed no disulfide bonds.<sup>6</sup>

To investigate the polypeptide chain make-up of this protein, we prepared modified paramyosin in the same medium as tropomyosin, the only difference being that the concentration of the paramyosin solvent was 7.5 M. Measurements of the same macroscopic properties were made (Table I, rows labeled I and II). Two differences in technique used in the paramyosin study are noteworthy: (1) molecular weights in benign medium were measured by the Archibald method; (2) since it is very difficult to determine the molecular weight in 7.5 M guanidine by absolute methods (because of strong nonideality), we have used the use of the intrinsic viscosity-molecular weight relationship for proteins<sup>9</sup> and have confirmed this by use of the sedimentation-viscosity relationship for random coils.<sup>10</sup>

Results for paramyosin are analogous to those for tropomyosin. Modified and unmodified paramyosins, for example, markedly different intrinsic viscosities in benign denaturing solvent, that of the unmodified being larger. Since destruction of cross-links in a single-chain random coil would produce a size effect,<sup>9</sup> this observation suggests some dissociation of chains in the modified protein. The molecular weight data confirm this: the mass of the modified molecule in guanidine is one-half that of the native protein. That this chain separation is reversible is evident from comparison of the data for the modified and unmodified proteins in benign media; the data are indistinguishable.

From these conclusions can be drawn from the experimental results: (1) the molecules of both tropomyosin and paramyosin contain two individual polypeptide chains; (2) in both proteins, at least as they are usually found, the chains are joined by at least one disulfide bond (which has not been detected chemically in paramyosin<sup>6</sup>); and (3) the disulfide cross-bridging is, in some cases, unnecessary for maintenance of the protein conformation—even after all disulfides have been reduced and the resulting sulfhydryls acetylated, the  $\alpha$ -helix is recovered in benign media.

At least two of the three conclusions noted above should be stated without some equivocation. There is a

discrepancy between the data of John and A. G. Szent-Györgyi, *J. Am. Chem. Soc.*, 79, 248

and Noelken, Ph.D. Thesis, Washington University, St. Louis,

Table I, footnote e.

Table I, footnote f.

chance that the two chains are unanimously parallel, or unanimously antiparallel, in the unmodified double-helical molecules, but that after modification and redissolution in benign medium a mixture of double-helical molecules results, some having parallel chains and some antiparallel. The measurements reported here are responsive only to comparatively gross changes in molecular shape and cannot resolve this ambiguity. However, if a coiled coil owes its stability to knobs-into-holes packing, as has been suggested,<sup>11</sup> it seems quite unlikely that any side-to-side packing other than that characteristic of the native protein would be very stable.

Needless to say, several questions remain; among these is whether the two chains within an individual molecule are identical or different, and, if the latter, whether they can be chemically separated. If so, it would be particularly interesting, for the fundamental theory of stability of protein conformations, to see if a system containing only one of the chains would form an  $\alpha$ -helix in a benign medium. Thus far, no instance of a single protein  $\alpha$ -helix has been reported.

### Relief by Modification of Carboxylate Groups of the Calcium Requirement for the Activation of Trypsinogen

Sir:

The activation of bovine trypsinogen involves the removal of a highly anionic hexapeptide from the N-terminal region of the molecule.<sup>1,2</sup> MacDonald and Kunitz<sup>3</sup> had shown earlier that this process is greatly enhanced by divalent cations such as calcium. These ions seem to exert a directing influence by both promoting the formation of active trypsin from trypsinogen and precluding the formation of an "inert protein." Thus in the presence of calcium ions proteolysis is restricted to the single peptide bond between lysine-6 and isoleucine-7, all other lysyl and arginyl bonds being resistant to tryptic cleavage. In the absence of calcium ions proteolysis is retarded and becomes relatively

(2) P. Desnuelle and C. Fabre, *Biochim. Biophys. Acta*, 18, 29 (1955).

(3) M. R. MacDonald and M. Kunitz, *J. Gen. Physiol.*, 25, 53 (1941).

Figure 1. The course of activation in 0.1 M Tris-Cl, pH 8.1, at 0° of native (squares) and modified (circles) trypsinogen (3.5 mg/ml) in the presence (filled symbols) and absence (open symbols) of 0.05 M CaCl<sub>2</sub>.

nonspecific.<sup>4</sup> It is not clear how calcium confers specificity on the limited proteolysis.

A possible site of interaction of calcium with trypsinogen is suggested by the amino acid sequence of the activation peptide, which contains a cluster of four  $\beta$ -carboxylates in a tetrapeptide sequence<sup>1</sup> adjacent to the bond being cleaved. The present experiments were designed to examine the effect on the activation process of modification of these free carboxylate groups with amines under the influence of water-soluble carbodiimides. In recent years<sup>5-7</sup> such treatments at acid pH have proven to be specific for other protein carboxylates.

Preliminary experiments showed that trypsin (0.2 mM) retained 68% of its activity during a 15-min treatment at pH 4.5, 25°, with a 25-fold molar excess of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide in 1.0 M glycine ethyl ester.<sup>8</sup> The reaction was stopped by the addition of 1.0 M acetate, pH 3.6, and the reagent was removed by dialysis against 10<sup>-3</sup> M HCl at 0°.

Similar treatment of trypsinogen resulted in a derivative which could be 64% activated relative to the unmodified control (Figure 1). Significantly, even in the absence of CaCl<sub>2</sub>, the modified protein could be activated to the extent of about 46%, whereas with unmodified trypsinogen in the absence of CaCl<sub>2</sub> activation did not exceed 15%. The number of active sites estimated by measuring the <sup>32</sup>P incorporation during inactivation with <sup>32</sup>P-labeled diisopropyl phosphorofluoridate corresponded to the activity determined by rate assay with benzoyl-L-arginine ethyl ester as substrate.

A series of anionic peptides was isolated from the activation mixture containing glycine ranging from 0.6 to 2.5 g residues per mole in addition to valine, aspartic

acid, and lysine (Table I). In contrast, activation of unmodified trypsinogen yielded a single acidic peptide of the expected composition (Val, Asp<sub>4</sub>, Lys). The anionic peptides in Table I represent a 60% yield of the N-terminal peptides from the modified trypsinogen. This is greater than the amount predicted from its activability (42%), suggesting that not every tryptic cleavage between lysine-6 and isoleucine-7 was productive. This observation is in accord with the end group analyses (Table II) which invariably exceeded the expected yield of DNP-isoleucine. However, in the latter case autolysis could account for high values for these N-terminal residues.

Table I. Peptides Derived from the Activation of Modified Trypsinogen\*

Peptide	g residues of glycine found	Yield of peptide, $\mu$ moles	Yield, %
A	0.6	0.106	14
B1	1.7	0.140	18
B2	1.3	0.194	26
C	2.3	0.166	22
D	2.5	0.150	20
Total		0.756	100

\* The modified protein (13.4 mg/ml) was activated for 1.5 hr at 0° in the absence of CaCl<sub>2</sub> in mixtures containing trypsin (0.67 mg/ml) and 0.05 M N-ethylmorpholine acetate, pH 8.1. Peptides were separated from the protein on Sephadex G-25 and purified by paper electrophoresis at pH 6.5 and chromatography in 1-butanol-acetic acid-water, 3:1:1. Acid hydrolysis of the anionic peptides yielded valine, aspartic acid, and lysine in the ratio 1:4:1 in all cases, in addition to the indicated amounts of glycine. Peptides B1 and B2 were not completely separated from each other. The stoichiometric yield of activation peptide (assuming 100% activation), after correcting for analytical losses during the isolation procedure, would be 1.31  $\mu$ moles.

Table II. Protein N-Terminal Residues in Activation Mixtures\*

Ile + Leu	..	0.67	0.26	0.68
Ser	..	..	0.08	0.32

\* Trypsinogen or modified trypsinogen was activated with trypsin (3.5 mg/ml) with or without CaCl<sub>2</sub> as in Table I for 2 hr. The protein component was precipitated with trichloroacetic acid and end-group analysis was carried out with FDNB (H. Fraenkel-Conrat, J. I. Harris, and A. L. Levy, *Methods Biochem. Anal.*, 2, 359 (1955)) in 8 M urea.

The number of peptides found indicates that the extent of substitution with glycine ethyl ester varied. Further fractionation is required to determine whether the peptide fractions on the electropherogram are molecularly homogeneous. The nonintegral values of glycine may be due to molecular heterogeneity resulting from multiple substitution, partial ester hydrolysis, or side reactions of undetermined character.

The activability of carboxylate-modified trypsinogen in the absence of CaCl<sub>2</sub> suggests that the directive influence of calcium on the normal activation may be by an interaction with carboxylate groups of the native zymogen. The present data show that carboxylate

## lytine

Haplophytine<sup>1</sup> was first isolated by Snyder and his co-workers, who carried out an extensive investigation of its chemistry.<sup>2</sup> It is obtained as the principal alkaloid from *Haplophyton cymicidum* (Apocynaceae).<sup>2-4</sup> High resolution mass spectrometry<sup>4</sup> required the determination of its formula to  $C_{27}H_{16}N_2O_7$  (calcd mol wt, 480; found,  $m/e$  652.29148).<sup>4</sup> Acid cleavage of the crystalline compound (76%),  $C_{22}H_{14}N_2O_4$ , mol wt, 382; found:  $m/e$  382, mp 201–203°, gave structure I on the basis of its nmr spectrum (see  $\delta$  values) and the following data. Its infrared spectrum ( $CHCl_3$ ) shows a strong  $C=O$  band at 1710  $cm^{-1}$  (cf. cimicine,<sup>4</sup> cimicidine,<sup>4</sup> and dichotamine<sup>5</sup>),

OH or NH bands. Its ultraviolet spectrum [220  $m\mu$  ( $\epsilon$  28,700), 256 (5900), and 304 (2400)] is characteristic of an indole chromophore. Its mass spectrum shows a strong peak at  $m/e$  44, characteristic of the earlier work on haplophytine has been summarized by Snyder and his co-workers.<sup>4</sup>

trifactory elemental analytical data have been obtained in this investigation<sup>4</sup> for all compounds whose molecular formulas

5. Brown, Jr., H. Budzikiewicz, and C. Djerassi, *Tetrahedron* **19**, 731 (1963).

istic of lactonic alkaloids of the aspidospermine skeletal type.<sup>7,8</sup> Hydrogenation of the cleavage product gave a zwitterionic tetrahydro derivative, mp 265° dec, formed by saturation of the ethylenic double bond accompanied by hydrogenolysis of the lactone (cf. dihydrocimicine and dihydrocimicidine<sup>4</sup>). Esterification with diazomethane gave a glass,  $C_{22}H_{14}N_2O_4$ , whose mass spectrum showed the molecular ion peak  $m/e$  400 (base peak) and a single prominent fragment ion at  $m/e$  168, a pattern very characteristic of non-lactonic alkaloids of the aspidospermine type.<sup>9</sup> Reduction of the cleavage product with sodium borohydride gave a zwitterionic product the spectra of whose methyl ester demonstrated that reductive cleavage of the lactone alone had occurred. The mass spectrum of this ester showed a molecular ion at  $m/e$  398, confirming the extent of reduction; the absence of significant fragment ions at  $m/e$  166 and 179 excluded a formulation in which the ethylenic double bond of I is placed at C-6-7.<sup>9</sup> The position assigned to the double bond is also in better accord with the chemical shift of the C-2 proton and the fine splitting of the olefinic proton signals in the nmr spectrum of I.

The many common features of the spectra of I and those of haplophytine [ $\lambda_{max}^{H_2O}$  220  $m\mu$  ( $\epsilon$  48,500), 265 (14,300), and 305 (4500);  $\lambda_{max}^{CHCl_3}$  5.72 and 6.05  $\mu$ ;  $\delta^{CDCl_3}$  (ppm) 2.40 (~3 H), 3.00 (3 H), 3.17 (3 H), 3.65 (3 H), 3.72 (1 H), 5.55 (1 H, doublet,  $J = 10$  cps), 5.85 (1 H, doublet,  $J = 10$  cps), 6.27 (1 H, doublet of doublets,  $J = 7$  and 2.5 cps), 6.9–7.2 (3 H, multiplet), 9.04 (1 H, absent after  $D_2O$  wash)] showed that the structure of haplophytine is related to that of I by replacement of a hydrogen atom in the latter by a moiety  $C_{12}H_{12}N_2O_4$ . That the linkage is at C-15 as in II is indicated by the absence of a doublet ( $J = 8$  cps) in the nmr spectrum of haplophytine corresponding to the C-15 proton signal in the spectrum of I. Catalytic hydrogenation of haplophytine gave tetrahydrohaplophytine,  $C_{27}H_{18}N_2O_7$ , accompanied by spectral changes analogous to those occurring when I was converted to tetrahydro-I; acid cleavage of the methyl ester of O-methyltetrahydrohaplophytine,  $C_{15}H_{12}N_2O_4$ , gave tetrahydro-I.

The intensities of the ultraviolet maxima of haplophytine indicated that the  $C_{12}H_{12}N_2O_4$  moiety also possesses an indole system. This can be expanded to a 7-hydroxy-1-acylindole system on the basis of the relationship between the infrared and nmr spectra of haplophytine and the spectra of its O-substituted derivatives, as earlier deduced by Snyder.<sup>2,4</sup> The nmr signal at 6.27 ppm, which can be assigned to an aromatic proton coupled with *ortho* and *meta* protons, requires that the 7-hydroxy-1-acylindole system be unsubstituted at the C-4, -5, and -6 positions. The signal at 2.40 ppm indicated the presence of an aliphatic  $N-CH_3$  in the  $C_{12}H_{12}N_2O_4$  moiety, while the infrared spectrum showed that the third oxygen atom can only be present in an ether linkage.

(8) K. S. Brown, Jr., W. E. Sanchez L., A. de A. Figueiredo, and J. M. Ferreira Filho, *J. Am. Chem. Soc.*, **88**, 4984 (1966).

(10) The presence of this second aromatic ring is considered to account for the unusual shielding of the protons of one of the methoxyl groups in haplophytine; in I, where this second ring is absent, the chemical shifts of the protons of both methoxyl groups are normal.

Figure 1.

A single-crystal X-ray diffraction study of haplophytine dihydrobromide revealed the structure shown in III (see Figure 1). The following crystal data were

III

obtained for the dihydrobromide with Cu K $\alpha$  radiation: monoclinic, space group C2, with  $a = 25.535$ ,  $b = 7.490$ ,  $c = 18.861$  Å,  $\beta = 101^\circ 19'$ ,  $V = 3537.2$  Å<sup>3</sup>,  $Z = 4$ ,  $D_x = 1.530$ ,  $D_m = 1.528$  g/cm<sup>3</sup>.

Three-dimensional diffraction intensity data were recorded at room temperature on a Picker four-circle automatic diffractometer for 2001 independent reflections. The positions of the bromine atoms in the unit cell were deduced from a three-dimensional Patterson synthesis. After fixing the origin of the unit cell by setting the  $y$  coordinate of one of the bromine atoms at zero, the positions of these heavy atoms were used to calculate the phases of the observed structure amplitudes. Successive three-dimensional Fourier syntheses and structure factor calculations progressively disclosed the electron-density distribution of the molecule. The  $R$  factor ( $\sum ||F_o| - |F_c|| / \sum |F_o|$ ), is 8.4% with anisotropic temperature factors for the bromine atoms and isotropic for the light atoms excluding hydrogen. The bond distances and angles are within the range of accepted values.

There are two intramolecular hydrogen bonds in the molecule, as indicated by oxygen-oxygen distances of 2.6 Å. One of these is in the 7-hydroxy-1-acylindole system, and the other is between the tertiary alcoholic hydroxyl group and the oxygen atom of the most proximal methoxyl group. The effect of the latter bond is to fix the orientation of the two large moieties with respect to one another in the crystal lattice. The absolute configuration of the molecule was determined by the anomalous dispersion method and is as shown in III and in the accompanying perspective diagram, in which the positive  $y$  direction extends out of the page toward the viewer (i.e., conventional right-handed co-

ordinate system). Further refinements of the structure will be reported in detail in due course.

Consideration of structure III in relation to the chemical and spectroscopic properties of haplophytine and the observation that the dihydrobromide is reconverted to the latter at pH 8 lead to the assignment of structure IV to haplophytine. This structure also permits the assignment of structures to the transformation products of haplophytine described earlier.<sup>2</sup>

### Trimethylenemethane, C(CH<sub>2</sub>)<sub>3</sub>

Sir:

Theoretical treatments<sup>1,2</sup> of trimethylenemethane (II) predict a triplet ground state and a high delocalization energy relative to the classical structure of one double bond and two localized electrons. Trimethylenemethane, stable in low-temperature matrices, has recently been prepared by the photolysis of 4-methylen-1-pyrazoline<sup>3a</sup> or 3-methylenecyclobutanone,<sup>3b</sup> and the esr spectrum confirmed a triplet ground state. Trimethylenemethane and its derivatives have been postulated to explain the formation of "rearranged" methylenecyclopropanes in the pyrolyses<sup>4</sup> or photolyses<sup>5</sup> of 4-alkylidene-1-pyrazolines and in the thermal isomerization of methylenecyclopropanes.<sup>6</sup>

We have examined the gas-phase reaction of 2-iodomethyl-3-iodopropene (I)<sup>7</sup> with alkali metal vapor

(7) 2-Iodomethyl-3-iodopropene (mp 32–33°, bp 83–85° (10 mm)) was prepared by the reaction of KI in acetone on 2-chloromethyl-3-chloropropene (see ref 8).

as a possible method of generating trimethylenemethane (II). The diiodide I was vaporized and carried in a helium stream, which was then saturated with alkali metal vapor by passage through a fine spray of sodium-potassium alloy (<10 sec in the spray zone) at 228–267°. The products consisted of 1,4-dimethylenecyclohexane (III),<sup>9</sup> *p*-xylene, isobutene (IV), 1-butene, *cis*- and *trans*-2-butenes, and methylenecyclopropane.<sup>8</sup>

The sum of the yields of III and *p*-xylene remained constant from one reaction to another, totaling about 35%. However, their ratio varied considerably, suggesting that III is converted to *p*-xylene.

The C<sub>4</sub> products, formed in yields of about 30%, were consistently about one-half isobutene. Methylenecyclopropane is partially converted to the straight-chain butenes under the reaction conditions.

The high yields of 1,4-dimethylenecyclohexane and isobutene suggest the intermediacy of triplet-state trimethylenemethane. 1,4-Dimethylenecyclohexane is the expected product from the dimerization of two molecules of trimethylenemethane having opposite spins. Isobutene is also expected, being formed by abstraction of two hydrogen atoms from hydrocarbon or potassium hydride.

Methylenecyclopropane could result from (1) initial production of singlet trimethylenemethane or (2) ring closure of the triplet species with spin relaxation by contact with an alkali metal atom or a surface.

In contrast to the behavior of trimethylenemethane, the corresponding saturated diradical VI, formed from the reaction of 1,3-diiodo-2-methylpropane (V) with alkali metal vapor at 227–228°, gives methylenecyclopropane, isobutene, and isobutane in yields of 76.7, 3.3, and 0.2%, respectively. 1,4-Dimethylcyclohexane or other products due to dimerization were not detected.

(8) The same products were obtained from 2-chloromethyl-3-chloropropene, but in lower yield. The dichloride was prepared by the method of B. C. Anderson, *J. Org. Chem.*, **27**, 2720 (1962), and J. T. Gragson, K. W. Greenlee, J. M. Derfer, and C. E. Boord, *J. Am. Chem. Soc.*, **75**, 3344 (1953).

(9) 1,4-Dimethylenecyclohexane was identified by comparison of the infrared spectrum and the melting point of its tetrabromide with those given in the literature [F. Lautenschlaeger and G. F. Wright, *Can. J. Chem.*, **41**, 1972 (1963)]. The nmr spectrum had two singlets at 2.20 and 4.64 ppm in a respective ratio of 2:1.

Extensive studies<sup>10,11</sup> of 1,2-, 1,3-, 1,4-, and 1,5-diradicals testify to the insignificance of bimolecular reactions, such as dimerization and disproportionations, in competition with unimolecular ring closure and rearrangement.

Although the reaction of 2-iodomethyl-3-iodopropene with alkali metal vapor is a two-step process, formation of 1,4-dimethylenecyclohexane cannot be due to the coupling of two monoiodo radicals. If this were the case, the saturated diiodide would also give dimeric material.<sup>12</sup> Hence, the preference for the bimolecular formation of 1,4-dimethylenecyclohexane and isobutene rather than the unimolecular formation of methylenecyclopropane is due to the greater stability, the greater reluctance to internal cyclization, and the longer lifetime of triplet trimethylenemethane relative to the saturated 1,3-diradical.

The failure to isolate the trimethylenemethane dimers by the pyrolysis<sup>4</sup> or photolysis<sup>5</sup> of 4-alkylidene-1-pyrazolines, or the pyrolysis of methylenecyclopropanes,<sup>6</sup> indicates that either the concentration of triplet trimethylenemethane was too low for bimolecular coupling to be observed or that triplet trimethylenemethane was not an intermediate in these reactions. Dimerization would be the expected reaction of the triplet molecule, formation of methylenecyclopropanes for the singlet. Theoretical considerations support these conclusions.<sup>13</sup>

Triplet tetramethylcyclobutadiene (VII) has been proposed as an intermediate in the reaction of *cis*-3,4-dichlorotetramethylcyclobutene and alkali metal vapor.<sup>14</sup> It would thus be expected that reaction of a mixture of this dichloride and 2-iodomethyl-3-iodopropene with alkali metal vapor would lead to the simultaneous production of triplet tetramethylcyclobutadiene (VII) and trimethylenemethane (II), which could then couple to produce 3-methylene-1,5,6,7-tetramethylbicyclo[3.2.0]heptene (VIII).<sup>15</sup> The experiment yielded, in addition to the expected products from the individual reactions of II and VII, a single cross-coupling product VIII, in 7% yield based on either reactant. This result suggests that both trimethylenemethane and tetramethylcyclobutadiene had the same electronic state, triplet. Had trimethylenemethane

(10) E. J. Goldstein, Ph.D. Thesis, The Pennsylvania State University, 1964; R. J. Petersen, Ph.D. Thesis, The Pennsylvania State University, 1964.

(11) R. J. Crawford and A. Mishra, *J. Am. Chem. Soc.*, **88**, 3963 (1966).

(12) Iodoalkanes react at nearly every collision with atomic sodium [E. Warhurst, *Quart. Rev.* (London), **5**, 44 (1951)]. Since the iodine atoms in the precursor to trimethylenemethane are both allylic, they should react as fast or slightly faster than those in the saturated diiodide. Consequently, the rate of formation of trimethylenemethane is as great as or greater than the rate of formation of the saturated diradical.

(13) W. T. Borden, *Tetrahedron Letters*, 259 (1967).

(14) P. S. Skell and R. J. Petersen, *J. Am. Chem. Soc.*, **86**, 2530 (1964).

(15) The cross-coupling product VIII was identified on the basis of the following evidence: the mass spectrum had a parent peak at *m/e* 162 corresponding to the formula C<sub>12</sub>H<sub>18</sub>; the infrared spectrum showed absorbances at 5.91 (cyclobutene double bond), 7.28 (methyl group), 3.30, 6.00, and 11.35  $\mu$  (terminal methylene group); the nmr spectrum consisted of singlets at 1.02 and 1.41 ppm and multiplets centered at 2.00 and 4.64 ppm in ratio of 3:3:2:1, respectively.

added to a singlet tetramethylcyclobutadiene, the resulting triplet adduct would not have been expected to give only a single cross-coupling product, but rather a number of monocyclic compounds *via* reduction, or internal or external disproportionation. Therefore the cross-coupling product VIII was formed in a one-step process involving the simultaneous formation of both bonds. The analogous bicyclic product<sup>16</sup> was obtained using *cis*-3,4-dichlorocyclobutene<sup>17</sup> and 2-chloromethyl-3-chloropropene, thus implicating a triplet cyclobutadiene intermediate.

The combined observations indicate that trimethylenemethane was produced and that it exists in a relatively stable triplet state, as predicted by theoretical calculations and in agreement with the esr results.

(16) 3-Methylenebicyclo[3.2.0]hept-6-ene was identified on the basis of the following spectral evidence: the mass spectrum had a parent peak at *m/e* 106 corresponding to the formula  $C_8H_{10}$ ; the infrared spectrum showed absorption bands at 3.29 (vinyl hydrogen), 5.93 (cyclobutene double bond), 6.00, and 11.15  $\mu$  (terminal methylene group); the nmr spectrum consisted of a singlet at 5.91 ppm and multiplets at 4.83, 3.20, and 2.12 ppm in a ratio of 1:1:1:2, respectively.

(17) A generous sample of *cis*-3,4-dichlorocyclobutene was furnished by Professor C. D. Nenitzescu.

## A Simple Floating Localized Orbital Model of Molecular Structure

Sir:

Most molecules have an even number of electrons which are generally paired off to create a ground state which is a spectroscopic singlet. For such molecules and states the following quantum mechanical model is proposed.

Let there be a minimal set of  $n$  floating localized orbitals  $\varphi_i$  which are, in general, nonorthogonal and real, and let each one be occupied by a pair of electrons with opposing spin. The  $2n$ -electron wave function can then be written as a single normalized Slater determinant

$$\psi = |\varphi_1(1)\bar{\varphi}_1(2)\varphi_2(3)\bar{\varphi}_2(4)\dots\varphi_n(2n-1)\bar{\varphi}_n(2n)|$$

$$[1/(\sqrt{(2n)!} \det S)]$$

where the bars over certain orbitals indicate  $\beta$  spin as opposed to  $\alpha$  for the others, and  $\det S$  is the determinant of the orbital overlap matrix  $S$  with elements

$$S_{ij} = \int \varphi_i^* \varphi_j d\tau$$

Given the set of orbitals and the appropriate nonrelativistic Hamiltonian operator  $H$ , the mean energy  $E$  is calculated according to a formula adapted from one derived by Löwdin<sup>1</sup>

$$E = \int \psi^* H \psi d\tau = 2 \sum_{i,j} (ij|f) T_{ij} + \sum_{i,j,k,l} (ij|kl) (2T_{ij} T_{kl} - T_{il} T_{jk})$$

where

$$(ij|f) = \int \varphi_i^* h \varphi_j d\tau$$

are the kinetic and potential energy integrals with the one-electron operator  $h$ , and

$$(ij|kl) = \int \varphi_i^*(1) \varphi_j(1) \varphi_k^*(2) \varphi_l(2) (1/r_{12}) d\tau(1) d\tau(2)$$

are the electron repulsion energy integrals.  $T_{ij}$ 's are elements of the reciprocal orbital overlap matrix

$$T = S^{-1}$$

For a given set of nuclear coordinates  $E$  is minimized, according to the variation method, by a variation in parameters defining the orbitals. This will generate a potential energy surface. If a "full minimization" of  $E$  with respect to nuclear coordinates as well as orbital parameters is carried out, then the equilibrium configurations of the molecule will be predicted. The calculation is strictly *ab initio* with no semiempirical parameters.

In this simple model the orbitals are taken to be floating spherical Gaussian functions<sup>2</sup>

$$\varphi_i = (2/\pi \rho_i^2)^{1/4} \exp[-(r/\rho_i)^2]$$

where  $r_i$  is the radial distance from the center of the orbital and  $\rho_i$  is an "orbital radius" parameter which defines a sphere which includes about 74% of the orbital charge density. For each orbital the coordinates of the center as well as the orbital radius are parameters to be varied.

Minimization of  $E$  with respect to all parameters will automatically lead to a result which will satisfy both the virial theorem and the Hellmann-Feynman theorem.<sup>3</sup>

Table I presents typical results for a series of diatomic and polyatomic molecules by the full minimization procedure.

The calculated energies are, of course, well above experimental values since no electron correlation is included other than that between electrons of like spin due to the antisymmetrization inherent in the determinantal wave function. Also the energies must be higher than those of Hartree-Fock calculations since the latter are by definition the values obtained by all possible variations of the orbitals in a single determinantal wave function. Because the total energies are crude, it would be expected that dissociation energies would be unsatisfactory and no attempt has been made to calculate them.

<sup>a</sup> W. Kolos and C. C. J. Roothaan, *Rev. Mod. Phys.*, **32**, 205 (1960). <sup>b</sup> D. D. Ebbing, *J. Chem. Phys.*, **36**, 1361 (1962). <sup>c</sup> P. E. Cade and A. C. Wahl, quoted by G. Das, *ibid.*, **46**, 1568 (1967). <sup>d</sup> E. Clementi, *ibid.*, **36**, 33 (1962). <sup>e</sup> B. D. Joshi, *ibid.*, **46**, 875 (1967). <sup>f</sup> R. Moccia, *ibid.*, **37**, 910 (1962); **40**, 2164, 2176, 2186 (1964). <sup>g</sup> R. J. Buenker, S. D. Peyerimhoff, and J. L. Whitten, *ibid.*, **46**, 2029 (1967). <sup>h</sup> Observed values are taken from L. E. Sutton, Ed., "Interatomic Distances," Special Publication No. 18, The Chemical Society, London, 1965.

The calculated bond lengths are surprisingly close to the experimental values, on the average within 4.4%. Considering the crudeness of the model no such direct quantitative similarity would be expected. However, the model should give general trends which certainly are present.

Bond angles are not as successfully calculated although NH<sub>3</sub> and H<sub>2</sub>O are properly predicted to be pyramidal and bent, respectively. The angles are: H-N-H, 88.0° (obsd 106.6°); and H-O-H, 89.5° (obsd 104.5°).

Dipole moments (Debyes) are calculated to be: LiH, 6.56 (obsd 5.882); HF, 1.66 (obsd 1.98); H<sub>2</sub>O, 1.92 (obsd 1.84); and NH<sub>3</sub>, 1.71 (obsd 1.46).

LiH is a simple example which shows how the orbital parameters behave. One orbital turns out to have a small "radius,"  $\rho$ , equal to 0.707 bohr and is located 0.0076 bohr from the Li nucleus on the side opposite from the proton. This can be considered an inner-shell Li orbital. The other orbital has a radius of 2.44 bohrs and is located about 89% of the way from Li to H. The bond could therefore be interpreted to be predominantly ionic.

This model has a simpler relation to the original electron pairing and shared pair concepts of Lewis<sup>4</sup>

than does the quantum mechanical valence bond method since the present model uses only one orbital per electron pair bond instead of two. It is also related to molecular orbital theory through the use of a single determinantal wave function. Localized molecular orbitals have been discussed particularly by Lennard-Jones and co-workers<sup>5</sup> and by Edmiston and Ruedenberg.<sup>6</sup>

This model constitutes an extension of the Kimball-Neumark<sup>7</sup> spherical Gaussian orbital model which was applied by Neumark to the simple systems He and H<sub>2</sub>. The "charge cloud" model of Kimball<sup>7</sup> which conceives of uniformly charged spheres for electron pairs resembles the present model but does not allow for overlap of the spheres and is only pseudo-quantum mechanical. Likewise the tangent-sphere model of Bent<sup>8</sup> and related ideas of King,<sup>9</sup> although giving considerable qualitative insight into molecular structure, are not sufficient for quantitative calculations. Details of the calculations and additional results will be published elsewhere.

## The Coordination Number of Aluminum(III) in Liquid Ammonia<sup>1</sup>

Sir:

Various nmr techniques<sup>2-4</sup> have been used to determine hydration numbers of ions in aqueous solutions. We have attempted to extend these methods to liquid ammonia and wish to report the results for Al(III) solutions. The method used was to determine the area under the <sup>14</sup>N nmr absorption line in the species Al(NH<sub>3</sub>)<sub>3</sub><sup>2+</sup> after broadening the solvent line beyond detection by addition of Cu(II). The exchange of bound ammonia in the Cu(II) complex is very rapid.<sup>5</sup> The area measurements were calibrated using various known species.

(1) Report No. RLO-1031-6 of work supported by the U. S. Atomic Energy Commission.

(2) J. A. Jackson, J. F. Lemons, and H. Taube, *J. Chem. Phys.*, **33**, 553 (1960).

(3) R. E. Connick and D. N. Fiat, *ibid.*, **38**, 1349 (1963).

(4) D. N. Fiat and R. E. Connick, *J. Am. Chem. Soc.*, **88**, 4754 (1966).

(5) J. P. Hunt, H. W. Dodgen, and F. Klanberg, *Inorg. Chem.*, **2**, 478 (1963).

Anhydrous aluminum iodide was prepared by standard methods and dissolved in anhydrous ammonia which was also prepared and handled by standard techniques. The Al(III) concentration was *ca.* 1.35 *M*. In other experiments it had been found that addition of  $\text{Cu}(\text{NH}_3)_4(\text{NO}_3)_2$  to the extent of *ca.* 0.2 *M* broadened the solvent ammonia line beyond detection (the bound ammonia line and solvent line occur at essentially the same frequency) and that Cu(II) and I<sup>-</sup> were stable in ammonia. Addition of the Cu(II) nitrate salt caused precipitation of some Al(III) the amount of which was determined, and an appropriate correction was made. The  $^{14}\text{N}$  nmr absorption line for the bound ammonia (and references) was measured at *ca.* 9300 gauss using equipment previously described.<sup>6</sup> The areas under the curves were measured in various ways and compared with areas obtained for standard aqueous  $\text{NaNO}_3$ ,  $\text{Co}(\text{NH}_3)_6^{3+}$  in ammonia,  $\text{Co}(\text{NH}_3)_6 \cdot \text{H}_2\text{O}$  in water, and others. The known solutions gave internally consistent results and were chosen to give line widths and intensities comparable to that found for the Al(III) species. This was done so that all the nmr measurements could be made under essentially identical conditions of radiofrequency level, modulation amplitude, etc. The full width at half-maximum absorption for the bound ammonia line was  $1.35 \pm 0.14$  gauss at  $27^\circ$ . The coordination number of Al(III) was found to be  $6.03 \pm 0.45$  (as an average of four signals).

We were unable to shift the solvent line sufficiently to be useful using either Cu(II) (which produces relatively small shifts) or Co(II) without causing excessively large amounts of broadening. Dysprosium nitrate was found to be too insoluble in ammonia to be useful for shifting the solvent line.

The results imply a relatively long lifetime for the  $\text{Al}(\text{NH}_3)_6^{3+}$  species in ammonia consistent with the results of Sutter and Hunt<sup>7</sup> using  $^{15}\text{N}$  tracer techniques. A coordination number of six was also found for the hydrated species.<sup>3</sup> The precision of the measurements was limited because of the broad, weak signals involved. Attempts to measure solvation number for Be(II) and Ga(III) have failed so far because of solubility problems. The use of  $^{15}\text{N}$  and improved nmr equipment may make it possible to study other species in the future.

## Oxidation of Coordinated Ligands. Sulfato and Nitrato Complexes of Platinum

Sir:

During the recent upsurge in interest in the behavior of  $d^{10}$  and  $d^8$  complexes, a variety of working models have been suggested in an attempt to rationalize and predict the chemistry of these species.<sup>1,2</sup> Recently

(1) C. D. Cook and G. S. Jauhal, *Inorg. Nucl. Chem. Letters*, **3**, 31 (1967).

(2) J. P. Collman and J. W. Kang, *J. Am. Chem. Soc.*, **88**, 3459 (1966).

we have inclined strongly to the view that the behavior in solution of the zerovalent complexes  $\text{M}(\text{PPh}_3)_4$  ( $\text{M} = \text{Ni}, \text{Pd}, \text{Pt}$ ) is essentially that of solvated metal atoms. The characteristics<sup>1</sup> of the oxygen and ethylene complexes,  $(\text{PPh}_3)_2\text{PtO}_2$  and  $(\text{PPh}_3)_2\text{Pt}(\text{C}_2\text{H}_4)$ , helped to reinforce this concept and prompted an investigation under homogeneous conditions<sup>3</sup> of those reactions in which platinum has traditionally served as a heterogeneous catalyst; *e.g.*, the contact process.

Passage of  $\text{SO}_2$  into a solution of  $(\text{PPh}_3)_2\text{PtO}_2$  at room temperature results in the rapid formation of an air-stable complex which we believe to be the sulfato complex I. *Anal.* Calcd for  $\text{C}_{36}\text{H}_{30}\text{O}_4\text{P}_2\text{Pt}$ : C, 53.00; H, 3.68; mol wt, 815. Found: C, 52.92; H, 3.66; mol wt, 795.

The infrared spectrum (Nujol) shows four strong band with some splitting at 1279, 1165 and 1150, 880 and 871, and 650  $\text{cm}^{-1}$ , which is in accord with the symmetry of the  $\text{SO}_4$  group acting as a bidentate ligand ( $\text{C}_{2v}$ ) and is in reasonable agreement with the spectrum reported by Barraclough and Tobe<sup>4</sup> for the complex  $[\text{Co}(\text{en})_2\text{SO}_4]\text{Br}$ , one of the few monomeric complexes known to contain bidentate sulfate. The possibility of a sulfur-bonded sulfito complex<sup>5</sup> cannot be ruled out in terms of the number of bands observed, but is, we feel, unlikely in view of the high frequency of the band which we assign to the asymmetric S-O stretch (1279  $\text{cm}^{-1}$ ). Reaction between  $\text{SO}_2$  and a solution of the ethylene adduct,  $(\text{PPh}_3)_2\text{Pt}(\text{C}_2\text{H}_4)$ , results in displacement of ethylene and formation of a brown crystalline complex<sup>6</sup> which loses  $\text{SO}_2$  readily on warming ( $50^\circ$ ) to yield the air-stable, green complex  $(\text{PPh}_3)_2\text{Pt}(\text{SO}_2)$ . *Anal.* Calcd for  $\text{C}_{36}\text{H}_{30}\text{O}_2\text{P}_2\text{Pt}$ : C, 55.17; H, 3.83; S, 4.09. Found: C, 54.92; H, 3.94; S, 4.68. Two strong infrared bands (Nujol) are found at 1182 and 1149 and 1035  $\text{cm}^{-1}$ , resulting from asymmetric and symmetric S-O stretching vibrations. The spectrum is strongly indicative of a sulfur-bonded  $\text{SO}_2$  adduct, and the complex is presumably of a similar type to  $(\text{SO}_2)\text{IrCl}(\text{CO})(\text{PPh}_3)_2$  recently reported by Vaska.<sup>7</sup> Passage of oxygen through a solution of the green  $\text{SO}_2$  adduct, or heating the complex in air ( $110^\circ$ ), results in the formation of the sulfato complex already described.

Similar results are obtained when the oxygen adduct is treated with  $\text{NO}_2$ , the dinitrato complex (II) being obtained pure and in high yield. *Anal.* Calcd for  $\text{C}_{36}\text{H}_{30}\text{N}_2\text{O}_6\text{P}_2\text{Pt}$ : C, 51.25; H, 3.56; N, 3.32. Found: C, 51.43; H, 3.65; N, 3.16. The complex

(3) It has recently been shown by G. Wilke, H. Schott, and P. Heimbach, *Angew. Chem. Intern. Ed. Engl.*, **6**, 92 (1967), that a solution of complex  $(\text{PPh}_3)_2\text{NiO}_2$  functions as a catalyst for the oxidation of triphenylphosphine.

(5) G. Newman and D. B. Powell, *Spectrochim. Acta*, **19**, 213 (1963).

(6) We have learned of closely related experiments by J. I. Levison and S. D. Robinson, *Chem. Commun.*, 198 (1967), following submission of this paper. They report the preparation of the brown, apparently four-coordinated adduct,  $(\text{PPh}_3)_2\text{PtSO}_2$ , and its ready oxidation to the sulfato complex,  $(\text{PPh}_3)_2\text{PtSO}_4$ , described herein.

(7) L. Vaska and S. S. Bath, *J. Am. Chem. Soc.*, **88**, 1333 (1966).

absorbs strongly at 1502 and 1491, 1272 and 1263, 974, and 787  $\text{cm}^{-1}$  in the infrared (Nujol) and is evidently comparable to a series of four-coordinate dinitrato complexes reported by Bannister and Cotton.<sup>8</sup>

The dinitrato complex is decomposed rapidly by boiling water with the liberation of nitrate ion; the sulfato complex is considerably more resistant to hydrolysis, but reaction with cyanide ion results in displacement of the coordinated sulfate group and formation of a cyano complex of Pt(II) (infrared band at 2132  $\text{cm}^{-1}$ ).

The mechanistic aspects of some of these reactions are currently receiving attention.

**Acknowledgment.** We thank the National Research Council of Canada and Engelhard Industries (Canada) Ltd. for their support.

### Delocalization of the $\pi$ -Electron System in 1,4-Dihydrophospha(V)pyrazines

Sir:

The nature of  $\pi$ -electron delocalization in the phosphonitrilic system has been the subject of some controversy.<sup>1,2</sup> The few cyclic phosphorus-carbon six- $\pi$ -electron systems capable of 3d-2p  $\pi$  delocalization thus far synthesized have been rather unstable.<sup>3,4</sup>

We wish to report the synthesis of a stable 1,4-dihydrophospha(V)pyrazine in which there appears to be delocalization of the four  $\pi$  electrons over the phosphorus atoms.

We have isolated 1,1,2,4,4,5-hexaphenyl-1,4-diphosphoniacyclohexadiene-2,5 dibromide (Ia) in over 60% yield from the 100-hr reaction of phenylethynyl-diphenylphosphine<sup>5</sup> (II) with hydrogen bromide in glacial acetic acid at room temperature (eq 1). The orange solid

Ia melted at 286–290° (from ethyl acetate-methanol). *Anal.* Calcd for  $\text{C}_{40}\text{H}_{32}\text{P}_2\text{Br}_2 \cdot \text{H}_2\text{O}$ : C, 63.83; H, 4.52; P, 8.24; Br, 21.28. Found: C, 63.85; H, 4.49; P, 8.30; Br, 21.05.

The water solubility, the infrared spectrum, and the fact that it gives an immediate yellow precipitate (Ib)

when treated with aqueous sodium picrate show that Ia is a phosphonium salt.

Elemental analysis establishes Ia as a 1:1 adduct of II and HBr, i.e.,  $[(\text{C}_6\text{H}_5)_2\text{PC}\equiv\text{CC}_6\text{H}_5 \cdot \text{HBr}]_n$ , while the lack of covalently bound bromine in the adduct is deduced from the analysis of the picrate Ib, mp 245–248° (from acetonitrile). *Anal.* Calcd for  $\text{C}_{33}\text{H}_{38}\text{N}_6\text{O}_4\text{P}_2$ : C, 60.58; H, 3.50; N, 8.16; Br, 0.00. Found: C, 60.50; H, 3.37; N, 8.14; Br, 0.00.

Table I\*

Compd	Protons	Multiplicity	$J_{\text{P-H}}$ , cps	$\tau$ , ppm	Area ratio
Ia	Vinyl	1	Broad complex	0.60	1
		1		1.04	
		1		1.5	
IIIa	Phenyl-P	Complex		2.0	10
	Phenyl-C	1		2.38	5
	CH	Complex		~4.6	1
	Phenyl	Complex		~2.2	15
	CH <sub>2</sub>	Complex		~5.6	2
IV	Vinyl	1	Broad complex	1.00	1
		1		1.42	
		1		1.84	
	Phenyl-P	Complex		2.15	10
	CH <sub>2</sub>	2 (broad)	8.0	6.11	2

\* Proton nmr at 60 Mc/sec employing tetramethylsilane as an internal standard and trifluoroacetic acid as solvent.

The proton nmr spectrum of a trifluoroacetic acid solution of Ia at 60 Mc (Table I) shows two sharp peaks at  $\tau$  0.6 and 1.5 with a shallow broad complex centered between them. This is similar to the proton nmr spectrum of 1,1,4,4-tetraphenyl-1,4-diphosphoniacyclohexene-2 dibromide (IV)<sup>6</sup> (Table I). These data

fit a polymeric vinylenebis(diphenylphosphonium) bromide.

Furthermore, the melting point and complete absence of covalently bound bromine strongly suggest a cyclic structure in which  $n$  is not very large.

Osmotic pressure depression of methanol solutions of Ia over a range of concentrations (Table II) showed that association occurs at higher concentrations and that the effective molecular weight, obtained by extrapolation, approaches the value of 245 (where  $n = 2$ ).

Table II. Molecular Weight Determination of Ia in Methanol Solution by Osmometric Method

Concentration		Mol wt
mg/ml	$M$	
9.470	0.0320	296
5.995	0.0212	283
3.280	0.0123	267

(6) A. M. Aguiar and H. J. Aguiar, *J. Am. Chem. Soc.*, **88**, 4090 (1966).

Hydrogenation of Ia employing 5% rhodium on alumina at 45 psi in methanol gave colorless 1,1,2,4,4,5-hexaphenyl-1,4-diphosphoniacyclohexane dibromide (IIIa), mp 269–272° (from acetonitrile-methanol). *Anal.* Calcd for  $C_{40}H_{48}Br_2P_2 \cdot H_2O$ : C, 63.49; H, 5.03; Br, 21.16; P, 8.70. Found: C, 63.33; H, 4.89; Br, 20.40; P, 8.77.

Compound IIIa was also produced by the reaction of *cis*- or *trans*- $\beta$ -styryldiphenylphosphines<sup>7</sup> (V) with hydrogen bromide in glacial acetic acid (eq 3). As in

the case of Ia, the structure of IIIa was established through elemental analysis, solubility, infrared spectrum, formation and analysis of a picrate (IIIb), and proton nmr spectra (Table I).

Compound IIIb had mp 230–233° (from acetonitrile). *Anal.* Calcd for  $C_{82}H_{40}N_6O_{14}P_2$ : N, 8.12; Br, 0.00. Found: N, 8.00; Br, 0.00. Absorption in the visible region by Ia is not understandable in terms of the delocalization present in a  $\beta$ -styryldiphenylphosphonium salt since the benzyl bromide salts of *cis*- and *trans*- $\beta$ -styryldiphenylphosphine (VI) are colorless.

Table III lists the ultraviolet absorbances of Ia and IIIa, along with those of *cis*- and *trans*-VI for comparison. Only a shoulder from the ultraviolet region was found in the visible spectrum of Ia.

Table III. Ultraviolet Absorptions of Methanol Solutions

Compd	$\lambda$ , m $\mu$	$\epsilon$
Ia	267 (peak emerging from large shoulder)	18,600
IIIa	269 (shoulder covering the 218 region)	4,600
<i>cis</i> -VI	270	1,100
	218	2,400
<i>trans</i> -VI	278	2,500
	217	3,000

Support for extensive delocalization of the  $\pi$  cloud is obtained from the  $^{31}P$  nmr data listed in Table IV.

Table IV\*

Compd	Shift
Ia	+3.5
IIIa	-20.4
IV	-2.8
<i>cis</i> -VI	-13.0

\* At 40.5 Mc/sec;  $^{31}P$  nmr shifts in parts per million of methanol solutions relative to an external standard of 85%  $H_3PO_4$ .

(7) A. M. Aguiar and T. G. Archibald, *Tetrahedron Letters*, **45**, 5541 (1966).

It is seen that the shielding of the phosphorus nucleus is substantially greater in Ia than in any other model compounds. In fact, Ia represents the first report of a phosphonium salt with a positive  $^{31}P$  nmr shift. Most simple phosphonium salts display  $^{31}P$  shifts in the -20- to -30-cps region.<sup>8,9</sup>

The above data are most easily accommodated by assuming delocalization of the  $\pi$ -electronic charge over the phosphorus atoms.

## Heavy-Atom Solvent Effect on the Photodimerization of Acenaphthylene

Sir:

Owing to their ability to enhance spin-orbit coupling, heavy-atom solvents have been used extensively in the study of singlet-triplet absorption and emission spectra.<sup>1</sup> In addition to an effect on the radiative processes, it is known that these solvents often promote nonradiative singlet-to-triplet intersystem crossing.<sup>2</sup> Two recent studies have attempted to make use of this external heavy-atom effect to affect increased intersystem crossing in photochemical reactions. However, no change was observed when heavy-atom solvents were used in a study of the type II photoelimination reactions of aliphatic ketones,<sup>3</sup> nor was an effect observed in the photodimerization of coumarin.<sup>4</sup> Both of these systems contain  $n-\pi^*$  excited states. El-Sayed<sup>5</sup> has pointed out that in carbonyl compounds the spin-orbit perturbation due to the carbonyl group is comparable to or larger than an internal heavy-atom perturbation due to halogen substitution on the carbonyl-containing molecule. In addition, the internal heavy-atom perturbation is expected to be much larger than the external perturbation due to a heavy-atom solvent.

In this note we wish first to present evidence to document the heavy-atom solvent effect on the photodimerization of a system not containing  $n-\pi^*$  states and second to show that in the two cases easily com-

(5) M. A. El-Sayed, *ibid.*, **41**, 2462 (1964).

pared that the effect is proportional to the square of the spin-orbit coupling factor ( $\zeta^2$ ).

It has been shown<sup>6,6a</sup> that the *cis* and *trans* dimers from the photolysis of acenaphthylene arise from two distinct excited states. The *cis* dimer is formed predominantly *via* an excited singlet state or more probably from a singlet excimer, while the *trans* dimer is formed *via* the triplet state. Since the probability of a singlet-triplet transition resulting from spin-orbit coupling depends inversely upon the square of the energy separation between the two states, one would expect a greater probability of crossing from a perturbed excited singlet to the triplet state than from the triplet to the ground state. Therefore, in the acenaphthylene system an increased triplet yield should result in an increased conversion to the *trans* isomer. The results of our experiments are shown in Table I. All photolyses were carried out using the apparatus and analytical procedure previously described.<sup>6</sup> As can be seen in Table I, both the total conversion to products and the relative amount of the *trans* dimer produced are markedly affected by the presence of a heavy atom in the solvent. For example, a change from pure cyclohexane to cyclohexane containing 10 mole % ethyl iodide increased, by a factor of 2, the total conversion and produced an 11-fold increase in the amount of *trans* dimer formed.<sup>7</sup> The amount of *trans* produced in propyl bromide solvents was found to be linearly dependent upon the mole per cent of propyl bromide for percentages where the total amount of conversion did not appreciably affect the probability of bimolecular reaction.

Table I. Heavy-Atom Solvent Effect on Photodimerization of Acenaphthylene

Solvent <sup>a</sup>	Total amount of dimer formed, g	Acenaphthylene recovered, g	<i>trans</i> , g	<i>cis</i> , g
Cyclohexane	6.51	8.40	1.09	5.42
Benzene	9.62	5.27	2.82	6.80
<i>n</i> -Butyl chloride	7.14	7.76	2.12	5.02
<i>n</i> -Propyl bromide in cyclohexane				
10 mole %	5.98	9.05	3.45	2.53
25 mole %	8.03	7.01	5.03	3.00
50 mole %	10.99	4.05	7.49	3.50
100 mole %	14.07	0.84	10.01	4.06
10% Ethyl iodide in cyclohexane	13.74	1.14	10.96	2.78

<sup>a</sup> All determinations were made with 15.2 g of acenaphthylene in 150 ml of solvent; irradiation time 15 hr.

The probability of a radiationless transition is proportional to the square of the perturbing operator in an expectation value equation involving the two states between which the transition is occurring. For transitions between states of different multiplicity, vibronic and/or spin-orbit perturbation operators are important.

(6a) NOTE ADDED IN PROOF. All solvents were essentially transparent at the wavelengths used (>3300 Å).

(7) A discussion of the *cis* dimer production is deferred until publication of the full paper since we have shown that the *cis* dimer arises from more than one excited state.

However, if there is strong electronic coupling of the excited states with the heavy-atom solvent states, the most important operator may generally be the spin-orbit operator.<sup>8</sup>

The probability then of an intersystem crossing from a singlet to a triplet state may be directly related to the square of the spin-orbit coupling factor  $\zeta$ , the values of which are known for atoms. Since the coupling is related to the atomic number of the perturbing nucleus, the relative magnitude of coupling may be approximated by using the coupling factor for the heaviest atom in the solvent. Thus, to a first approximation, the relative probability of intersystem crossing in proceeding from *n*-PrBr to EtI would be given by  $(\zeta_{\text{I}}/\zeta_{\text{Br}})^2$ . Using the values  $\zeta_{\text{I}} = 5060$  and  $\zeta_{\text{Br}} = 2460$ ,<sup>9</sup> this ratio becomes equal to 4.2. Using the data for the formation of *trans* dimer in Table I (10% *n*-PrBr, EtI) and correcting for the amount of *trans* formed in pure cyclohexane, the ratio  $\text{trans}_{\text{EtI}}/\text{trans}_{\text{PrBr}}$  is equal to 4.18. The agreement between these two ratios is excellent. Investigations of the effect of other heavy-atom solvents as well as a comparison of external and internal heavy-atom effects on the photodimerization are currently in progress.

## Formation of Spiroonatriene and Heptafulvalene from an Attempt to Generate Cycloheptatrienyliene

Sir:

If the normal electrophilicity<sup>1</sup> of a singlet carbene is sufficiently suppressed by delocalization of electrons into its vacant p orbital, its behavior should resemble that of a nucleophile as a result of the nonbonded pair of electrons on the carbene carbon. In a number of cases<sup>2</sup> where adjacent heteroatoms (oxygen, nitrogen)

(1) Cf. J. Hine, "Divalent Carbon," The Ronald Press, New York, N. Y., 1964, p 43; W. Kirmse, "Carbene Chemistry," Academic Press Inc., New York, N. Y., 1964, p 164.

(2) Although the question of the actual intermediacy of nucleophilic carbenes in many cases has been clouded by the fact that the carbene dimers (e.g., tetraaminoethylenes) give the same products with electrophiles<sup>1</sup> as would be expected from the carbene itself, there are still a number of cases that probably do indeed involve intermediate carbene formation (including, in fact, reactions of the dimer with electrophiles<sup>3</sup>). For examples of these as well as lead references to earlier work, see: D. M. Lemal, E. P. Gosselink, and S. D. McGregor, *J. Am. Chem. Soc.*, 88, 582 (1966); R. W. Hoffmann and H. Hauser, *Tetrahedron*, 21, 1891 (1965); H. Quast and S. Hunig, *Chem. Ber.*, 99, 2017 (1966); *Angew. Chem. Intern. Ed. Engl.*, 3, 800 (1964); H. Balli, *ibid.*, 3, 809 (1964); H. Quast and E. Frankenfeld, *ibid.*, 4, 691 (1965); H. W. Wanzlick and A. Hanns, *Chem. Ber.*, 99, 1580 (1966); H. W. Wanzlick and H. J. Kleiner, *Angew. Chem. Intern. Ed. Engl.*, 3, 65 (1964). For an excellent review of earlier work in this area, see H. W. Wanzlick, *ibid.*, 1, 75 (1962). For the first example of an intermediate of this type, see R. Breslow, *J. Am. Chem. Soc.*, 80, 3719 (1958).

(3) D. M. Lemal, R. A. Lovald, and K. I. Kawano, *ibid.*, 86, 2518 (1964); H. E. Winberg, J. E. Carnahan, D. D. Coffman, and M. Brown, *ibid.*, 87, 2055 (1965); N. Wiberg and J. W. Buchler, *Chem. Ber.*, 96, 3000 (1963).

have served as the electron-donating groups this anticipated effect has manifested itself in an inertness to typical alkenes but reactivity with a wide variety of electrophiles.

A second mechanism for delocalizing electrons into the vacant p orbital of a singlet carbene and thereby accentuating its nucleophilicity is its incorporation into a conjugated ring in such a way as to make the vacant orbital an integral part of an aromatic system. The simplest example of this type of system, the two- $\pi$ -electron cyclopropenylidene (1), has defied standard techniques for generating carbenes<sup>4,5</sup> but has been suggested as a possible intermediate in the reaction of a substituted cyclopropenyl carbamate with base. The evidence for this as an intermediate consists simply of the fact that it gives spiropentenes with electrophilic olefins<sup>6</sup> and no reaction with simple alkenes.<sup>4</sup>

At this time we wish to report the results of our attempts to generate a potentially nucleophilic carbene in which the vacant p orbital is an integral part of a six- $\pi$ -electron aromatic system—cycloheptatrienyli-dene<sup>7</sup> (3).

As a potential precursor to this species, tropone tosylhydrazone was synthesized in high yield from tropone *via* 7,7-dichlorocycloheptatriene. The tosylhydrazone was converted to its sodium salt (a muddy brown solid) with sodium hydride in tetrahydrofuran. Photolysis of the salt in tetrahydrofuran in the presence of typical alkenes gave the salt of *p*-toluenesulfonic acid and up to 50% of a photolytically unstable, almost black crystalline solid, but no indication of the spiro-natriene adduct that would result from carbene addition to the alkene double bond. The dark solid was identified as heptafulvalene (5) by comparison of its properties with those reported for an authentic sample.<sup>9</sup>

(4) Unpublished results from these laboratories.

(5) R. Breslow and L. J. Altman (*J. Am. Chem. Soc.*, **88**, 504 (1966)) have pointed out that perhaps one factor contributing to the acidity of the ring hydrogen of *n*-propylcyclopropenone is contribution of a cyclopropenylidene resonance form.

(6) W. M. Jones and M. E. Stowe, *Tetrahedron Letters*, 3459 (1964).

(7) Generation of di- and triannelated cycloheptatrienylenes has been recently reported by Murahashi, Moritani, and Nishino.<sup>8</sup> In view of the involvement of the aromatic rings in the conjugated systems of these intermediates, it is not surprising that their chemical properties resemble typical aryl-substituted alkylidenes.

(8) Cf. S. Murahashi, I. Moritani, and M. Nishino, *J. Am. Chem. Soc.*, **89**, 1257 (1967).

Even in the presence of electron-rich alkenes (*e.g.*, enamines) there was observed none of the spiro adduct but, again, only the dimer and sodium *p*-toluenesulfinate. However, when the photolysis was carried out in the presence of the electrophilic olefin, dimethyl fumarate, there was isolated, in addition to the sulfinate salt and the dimer, a 47% yield of the spiro-natriene 7 which, formally, would arise from addition of cycloheptatrienyli-dene to the fumarate double bond.

Both analyses<sup>10</sup> and spectra support the interesting structure assigned to 7. In the infrared it showed a single carbonyl absorption at 1720  $\text{cm}^{-1}$ , in the ultra-violet it showed a single maximum at 262  $\text{m}\mu$  ( $\epsilon$  2800), and in the nmr it showed single peaks at  $\tau$  7.65 (cyclopropyl hydrogens) and 6.32 (methyl hydrogens), a doublet at  $\tau$  4.59 (*ortho* ring hydrogens), and a multiplet at  $\tau$  3.52 (remaining cycloheptatriene ring hydrogens), with areas in the ratio 2:6:2:4, respectively. Additional support for the assigned structure resides in its facile conversion under acidic conditions to the corresponding heptafulvene 8. For example, 1% HCl

(10) All new compounds gave acceptable analyses.

ucts and reaction paths.<sup>2</sup> However, if benzenediazonium-2-carboxylate (1'), prepared directly from anthranilic acid and amyl nitrite,<sup>3</sup> is similarly decomposed, the reaction products<sup>4</sup> are 2 and biphenylene (5), accompanied with only *trace* amounts of 3 and 4 (run 1). These results are all the more unusual inasmuch as it has been shown<sup>5</sup> that benzyne generated from several different sources appears to behave the same.

The essential difference between 1 and 1' is that 1 is prepared in a silver ion environment<sup>1</sup> and 1' is not.<sup>3</sup> The apparent dependence of product distribution on the method of synthesis of benzenediazonium-2-carboxylate is a result of *silver ion contamination*. This was adequately demonstrated (Table I) by decomposing 1' in benzene, at 45°, containing known amounts of added Ag<sup>+</sup> as the oxide, trifluoroacetate, and perchlorate.<sup>6</sup> The effect of Ag<sup>+</sup> is clearly evident by observing the change in product composition in the absence of added Ag<sup>+</sup> (run 1) to that when the Ag<sup>+</sup>:1' is ~10<sup>-3</sup> (run 2). By increasing the Ag<sup>+</sup>:1' to ~10<sup>-2</sup> the amount of 2 formed is reduced to 3.7%.<sup>7</sup>

The results from reaction of benzyne with benzene in the presence of Ag<sup>+</sup> are best explained by proposing a benzyne-silver complex (6)<sup>8</sup> which would be more electrophilic than benzyne. The complex could attack benzene to give 7 which, by intra- or intermolecular H<sup>+</sup> transfer and ejection of Ag<sup>+</sup>, gives biphenyl (4) or,

(2) *E.g.*: (a) E. K. Fields and S. Meyerson, *Chem. Commun.*, 474 (1965); (b) S. F. Dyke, A. R. Marshall, and J. P. Watson, *Tetrahedron*, 22, 2515 (1966).

(3) Amyl nitrite (5 ml) was added to a solution of anthranilic acid (3.0 g) and trifluoro- or trichloroacetic acid (0.03 g) in THF (30 ml). After 1-1.3 hr the mixture is cooled to ~10°, and the off-white to pale yellow solid is collected and washed with THF until washings are colorless, and then with benzene. The yield of 1' varies between 92 and 95%. *Dry 1' is exceedingly hazardous*. Solvent (benzene) moist material (much less hazardous) was used in this study.

(4) Several other hydrocarbons are formed in this reaction. A major product, C<sub>18</sub>H<sub>14</sub>, mp 154-155° (6-10% yield), was identified (on the basis of its nmr spectrum) as hexacyclo[8.7.1.0<sup>2,7</sup>.0<sup>3,12</sup>.0<sup>1,11</sup>.0<sup>4,13</sup>]octadeca-2,4,6,11,13,15-hexaene (i). From reaction of 1' with 2 in refluxing

ethylene chloride i was prepared in >80% yield. This compound was also discovered in Professor Stiles' laboratory (M. Stiles, U. Burckhardt, and G. Freund, *J. Org. Chem.*, in press). The structure of i was confirmed by an X-ray crystallographic study: J. W. Schilling and C. E. Nordman, American Crystallographic Association Meeting, Atlanta, Ga., Jan 1967, Abstracts, p 22.

(5) R. Huisgen and R. Knorr, *Tetrahedron Letters*, 1017 (1963).

(6) The ratio of 3:4 is somewhat dependent of the anion, but not that of 2:(3 + 4). Compare 3:4 = 0.9 from run 8 which appears to be contaminated with about 0.1% Ag<sup>+</sup> as AgCl and/or Ag<sub>2</sub>O with that of ~0.6 from runs 2-7 containing AgClO<sub>4</sub>. This will be discussed in detail in the full paper.

(7) (a) 2, 3, 4, and 5 are not interconverted nor destroyed by the action of Ag<sup>+</sup>. (b) 1,4 Addition seems to be the usual reaction path of arynes with arenes. *Cf.* Reaction of tetrachlorobenzyne (from the Grignard reagent) and mesitylene (H. Heany and J. M. Jablonski, *Tetrahedron Letters*, 4529 (1966)); formation of dibenzobarralene in 30% yield from 1' and 2 equiv of naphthalene (this study) or from 1 and excess naphthalene in 7% yield;<sup>1</sup> ring A adducts (1,4) from benzyne and anthracenes (G. H. Klanderman, *J. Am. Chem. Soc.*, 87, 4649 (1965)). 4-Me-1' behaves similarly.

(8) Structures can be drawn which involve overlap of d orbitals of Ag<sup>+</sup> with the sp<sup>2</sup> orbitals and/or with the benzene  $\pi$  systems. For examples of silver olefin and silver dialkylacetylene complexes see F. R. Hapner, K. N. Trueblood, and H. J. Lucas, *ibid.*, 74, 1333 (1952); A. E. Comyns and H. J. Lucas, *ibid.*, 79, 4339, 4341 (1957), and references contained therein.

<sup>a</sup> Reaction temperature 45°. <sup>b</sup> Yield of C<sub>18</sub> hydrocarbons is ca. 20%. <sup>c</sup> Hydrocarbons separated on 10 ft × 0.25 in. o.d. 20% SE 30 on Chromosorb W 60-80 mesh, column 135°. Relative retention time: 2, 0.75; 3, 0.89; 4, 1.00; 5, 1.37; acenaphthene, 1.60 (internal standard). <sup>d</sup> Typical data. <sup>e</sup> Benzenediazonium-2-carboxylate prepared as described in ref 1.

by ring closure followed by valence bond isomerism, yields benzocyclooctatetraene (3). Thus, the ratio 2:(3 + 4) is a measure of the two competitive processes: (1) 1,4 addition of benzyne to benzene, and (2) benzyne-silver complex (6) formation and subsequent reaction with benzene<sup>9</sup> (Scheme I). The magnitude of the effect

Scheme I

of trace amounts of Ag<sup>+</sup> is indicative of the extraordinary catalytic ability of Ag<sup>+</sup> to "trap" benzyne and of the reactivity of 6.

In the "complete" absence of Ag<sup>+</sup>, benzyne reacts with benzene to give benzobarrelene by 1,4 addition.<sup>10</sup>

(9) The distribution of the isomeric methylbiphenyls formed from 1' and toluene in the presence of Ag<sup>+</sup> should either support or vitiate the proposed mechanism.

(10) (a) Pyrolysis of phthalic anhydride in benzene-*d*<sub>6</sub> at 690° gave a mixture of C<sub>18</sub> hydrocarbons in 48% yield (based on unrecovered phthalic anhydride) which consisted of biphenyl-*d*<sub>8</sub> (from benzyne and benzene) (~9.4%), naphthalene-*d*<sub>8</sub> (~81%), acenaphthylene (*d*<sub>8</sub>-*d*<sub>8</sub>) (~6%), and acenaphthene (*d*<sub>8</sub>-*d*<sub>8</sub>) (~5%). In addition extensive

iphenylene (5) is a result of benzyne dimerization insured since 5 obtained by decomposing 1' in benzene- $d_6$  was found to be deuterium free, 2, C-D stretch absent in the infrared.

of the other metal ions ( $Tl^+$ ,  $Cu^+$ ,  $Cu^{2+}$ ,  $Hg^{2+}$ )<sup>11</sup> screened thus far altered the course of benzyne-benzene reaction. The study is being extended however, to transition metals and their complex in anticipation that an isolable benzyne complex may result.<sup>12</sup>

of biphenyl- $d_{10}$  were formed *via* benzene- $d_6$  thermal dimerization: biphenyl- $d_6$ :biphenyl- $d_{10}$   $\sim 0.1$ . Biphenylene was not detected. Acenaphthylene and acenaphthene are formed *only* by thermal decomposition of 3. Based on isolated and characterized hydrocarbon, it can be concluded that at 690° the major reaction of benzyne with benzene is 1,4 addition ( $\sim 75\%$ ) to give 2, followed by loss of 2 to give thermally stable naphthalene. The balance is electrocyclic (*vide supra*) to give 4 ( $\sim 10\%$ ) and 3 ( $\sim 15\%$ ) (which re-arrange to form acenaphthene, which in turn is partially deoxygenated to acenaphthylene) and pyrolysis (40%) to naphthalene. Results are somewhat different from earlier reports<sup>13</sup> (D. F. Lindow, unpublished data). (b) Cf. G. M. Badger, *Progr. Phys. Org. Chem.*, 1 (1966).

The absence of any effect is a strong argument against benzyne as a benzene-metal complex.

The assistance of L. R. Rice and D. F. Lindow in carrying out the initial experiments is gratefully acknowledged.

## cyclopropenone

Studies of various cyclopropenones, including dicyclopentenone,<sup>1</sup> the earliest example, and the recent monoalkylcyclopropenones,<sup>2</sup> have fully shed the unusual stability of this strained system. Chemical properties of importance have also been investigated on these derivatives.<sup>1-3</sup> However, although the parent ketone III is clearly of interest, it resisted our synthetic attempts to prepare it by the methods used to make substituted derivatives. We have now succeeded in synthesizing unsubstituted cyclopropenone.

Reaction of tetrachlorocyclopropene<sup>4</sup> (I) with 2 equivalents of tri-*n*-butyltin hydride at room temperature in an oil produced a volatile mixture<sup>5</sup> of chlorocyclopropenes containing 3,3-dichlorocyclopropene (II) ( $\delta$  8.0), 1,3-dichlorocyclopropene ( $\delta$  7.2, 4.5, 2 cps), and mono- and trichlorocyclopropene. The distilled mixture was taken up in  $CCl_4$  and continuously hydrolyzed with cold water (or  $D_2O$ ). The aqueous phase contained as the only detectable product cyclopropenone (the solvent peak could be moved by adding sodium phosphate or removed by using  $D_2O$ ) a

sharp singlet at  $\delta$  9.0 which we assign to the protons of cyclopropenone (III).

The nmr spectrum unambiguously establishes this structure. Thus the singlet shows  $^{13}C$  satellites with the very large coupling ( $J_{C-H} = 230$  cps) characteristic of a cyclopropene<sup>6</sup> or acetylene. The latter is, of course, excluded by the chemical shift of  $\delta$  9.0; this also excludes nonketonic cyclopropene structures since 1,3,3-trimethylcyclopropene has its vinyl proton at  $\delta$  6.7 and the 3,3-dichlorocyclopropene signal is at  $\delta$  8.0, while methylcyclopropenone is at  $\delta$  8.7. The  $^{13}C$  satellites of III appear, as expected, as a doublet ( $J_{H-H} = 3$  cps).

The aqueous solution of III shows broad infrared absorption centered at  $1850\text{ cm}^{-1}$ . On standing it slowly ( $t_{1/2}$  at  $25^\circ > 1$  week) is hydrolyzed to acrylic acid.<sup>8</sup> Treatment with alkali produces a dark polymer, but the compound is stable to a variety of strong mineral acids. Although III is very polar, it can be extracted from the water solution with methylene chloride or ethylene chloride by salting out. The protons in III are still at  $\delta$  8.9-9.0, there are no other signals in the nmr, and the infrared spectrum shows a strong cyclopropenone doublet<sup>9</sup> at 1835 and  $1870\text{ cm}^{-1}$  and no absorption in the O-H region. Thus III is apparently present as the free ketone, rather than a gem-diol, even in aqueous solution.

Attempts to isolate III by removal of solvent, distillation, or vapor phase chromatography under a variety of conditions have so far failed, leading to at least partial polymerization of the compound; the parent ketone is apparently more sensitive than its derivatives. However, the low reactivity of III compared with cyclopropanone,<sup>10</sup> and in particular its retention of the unhydrated carbonyl group in water solution, confirm our previous conclusion that the cyclopropenone system has considerable conjugative stabilization.

**Acknowledgment.** We gratefully acknowledge support of this work by the National Institutes of Health, and thank Mr. John Groves for several experimental contributions.

(6) Methylcyclopropenone<sup>6</sup> has  $J_{C-H} = 213$  cps and 1,3,3-trimethylcyclopropene<sup>7</sup> has  $J_{C-H} = 218$  cps.

though the allylic chlorines must be most reactive, the resulting cyclopropenyl radical may pick up hydrogen on any ring and the cyclopropenyl chlorides undergo rapid allylic isomerization.

Under appropriate conditions the essentially pure mixture of 3 can be prepared. On treatment with  $AgBF_4$  in a variety of solvents, Mr. John Groves has found that this affords chlorocyclopropenone, with an nmr singlet at  $\delta$  9.6 ( $J_{C-H} = 242$  cps,  $J_{H-H} = 2$

Chart I. Oxidation of Singlet Oxygen Acceptors by 9,10-Diphenylanthracene Peroxide

cene undergo photosensitized autooxidation to form transannular peroxides,<sup>1</sup> and a number of recent reports have provided strong evidence indicating that singlet oxygen is involved in the formation of these "photoperoxides."<sup>2</sup> It is also well known that many of these peroxides undergo dissociation on heating to regenerate oxygen and the parent hydrocarbon. The ease of oxygen release from these systems depends on the polycyclic aromatic system and the nature of the substituents in the *meso* positions.<sup>3</sup>

We now report that 9,10-diphenylanthracene peroxide (II) may be used to bring about typical singlet oxygen reactions when it is allowed to decompose.<sup>4,5</sup>

(1) The first example of an aromatic transannular peroxide, rubrene peroxide, was reported by C. Moreau, C. Dufraisse, and P. M. Dean, *Compt. Rend.*, 182, 1440, 1584 (1926). For a recent review, see Y. A. Arbuzov, *Russ. Chem. Rev.*, 34, 558 (1965).

(2) C. S. Foote and S. Wexler, *J. Am. Chem. Soc.*, 86, 3879, 3880 (1964); C. S. Foote, S. Wexler, and W. Ando, *Tetrahedron Letters*, 46, 4111 (1965); E. J. Corey and W. C. Taylor, *J. Am. Chem. Soc.*, 86, 3881 (1964); T. Wilson, *ibid.*, 88, 2898 (1966); E. McKeown and W. A. Waters, *J. Chem. Soc., Sect. B*, 1040 (1966).

(3) For a review, see W. Bergmann and M. J. McLean, *Chem. Rev.*, 28, 367 (1941).

(4) C. Dufraisse and L. Enderlin, *Compt. Rend.*, 191, 1321 (1930); C. Dufraisse and J. LeBras, *Bull. Soc. Chim. France*, 4, 349 (1937).

(5) Preliminary kinetic studies on the thermal decomposition of 9,10-diphenylanthracene peroxide in methylene chloride at 90° indicate a first-order rate constant for oxygen release of  $2.5 \times 10^{-4} \text{ sec}^{-1}$  ( $t_{1/2}$  8 hr). This value is considerably faster than the rate of decomposition of tertiary peroxides such as *t*-butyl or trityl (which, furthermore, decomposes by peroxide bond cleavage) and suggests that 9,10-diphenyl-

anthracene peroxide undergoes a concerted oxygen release (E. Hedaya, private communication).

anthracene peroxide undergoes a concerted oxygen release (E. Hedaya, private communication).

# **The Isolation and Structural Elucidation of Thalidasine, a Novel Bisbenzylisoquinoline Alkaloid Tumor Inhibitor from *Thalictrum dasycarpum*<sup>1,2</sup>**

Sir:

The genus *Thalictrum* has served as a uniquely profuse source of new and novel benzylisoquinoline and aporphine alkaloids.<sup>3-6</sup> We report herewith the isolation and elucidation of the structure (Ia) of thalidasine, a new alkaloid tumor inhibitor<sup>7</sup> from *T. dasycarpum*. Thalidasine appears to be the first bisbenzylisoquinoline recognized to contain a diphenyl ether terminus at C-5 and the first unsymmetrical bisbenzylisoquinoline recognized to contain a 20-membered ring.<sup>8</sup> Furthermore, the alkaloid thalfoetidine, from *T. foetida*,<sup>9</sup> is shown to possess structure Ib on the basis of evidence which includes interrelation with thalidasine.

Thalidasine (Ia), C<sub>29</sub>H<sub>44</sub>N<sub>2</sub>O<sub>7</sub>, mol wt (mass spectroscopy)<sup>10</sup> 652, is an amorphous solid, mp 105-107°, [ $\alpha$ ]<sub>D</sub><sup>25</sup> -70° (c 0.89, MeOH),  $\lambda_{\text{max}}^{\text{EtOH}}$  275 m $\mu$  ( $\epsilon$  4560), 282 m $\mu$  ( $\epsilon$  4530), and nmr signals (in CDCl<sub>3</sub>) at  $\tau$  7.38, 7.75 (6 H, two NCH<sub>3</sub>), 6.09, 6.13, 6.25, 6.50, 6.73 (15 H, five OCH<sub>3</sub>), and 2.46-3.70 (9 H, aromatic H). The alkaloid was characterized as the oxalate, mp 160-

162°, picrate, mp 175-177°, and methiodide, mp 182-183°. Permanganate oxidation of Ia yielded 2-methoxydiphenyl ether 4',5-dicarboxylic acid (V), characterized by mixture melting point and infrared comparison with an authentic sample.<sup>11</sup> Sodium in liquid ammonia reduction of Ia afforded, as principal products, L-O-methylarmepavine (IIa), mp 61-62°, [ $\alpha$ ]<sub>D</sub><sup>25</sup> +99° (c 1.10, CHCl<sub>3</sub>), and a dihydroxydimethoxybenzylisoquinoline (A), C<sub>19</sub>H<sub>23</sub>NO<sub>4</sub>, mp 194-196°, [ $\alpha$ ]<sub>D</sub><sup>25</sup> +51° (c 0.50, MeOH),  $\lambda_{\text{max}}^{\text{EtOH}}$  279 m $\mu$  ( $\epsilon$  2750), nmr signals at  $\tau$  7.48 (3 H, NCH<sub>3</sub>), 6.13, 6.45 (6 H, two OCH<sub>3</sub>), 4.33 (1 H, C-8 H), 3.92 (2 H, two OH), 3.08, 3.35 (4 H, two doublets,  $J$  = 8.5 cps). Methylation of phenol A with diazomethane gave 1-(4-methoxybenzyl)-2-methyl-5,6,7-trimethoxy-1,2,3,4-tetrahydroisoquinoline (IIIa), characterized by infrared and nmr comparison with the *dl* compound.<sup>4b</sup> Nmr spectral characteristics and reactivity toward Gibbs reagent<sup>12</sup> led to consideration of 4',6-diphenol (IIIb) and 4',5-diphenol (IIIc) structures as most likely for

phenol A. However, the infrared spectrum of synthetic [via the dibenzyl ether IIId, mp 83-86°, nmr signals at  $\tau$  7.49 (3 H, NCH<sub>3</sub>), 6.19, 6.55 (6 H, two OCH<sub>3</sub>), 4.97, 5.02 (4 H, two OCH<sub>2</sub>Ph), 3.02, 3.13 (4 H, two doublets,  $J$  = 8.5 cps, disubstituted aromatic

(7) Thalidasine showed significant inhibitory activity against Walker intramuscular carcinosarcoma 256 in rats at 200 mg/kg. Tumor inhibitory activity was assayed, under the auspices of the Cancer Chemotherapy National Service Center, National Cancer Institute, National Institutes of Health, by the procedures described in *Cancer Chemotherapy Rept.*, 25, 1 (1962).

(8) Cissampareine was the first symmetrical bisbenzylisoquinoline recognized to contain a 20-membered ring (S. M. Kupchan, S. Kubota, E. Fujita, S. Kobayashi, J. H. Block, and S. A. Telang, *J. Am. Chem. Soc.*, 88, 4212 (1966)).

(9) N. M. Mollov and V. St. Georgiev, *Chem. Ind. (London)*, 1178 (1966).

(10) The authors thank Professor A. L. Burlingame and Dr. H. K. Schnoes, University of California, Berkeley, for the mass spectral data and helpful discussions.

ring), 2.63 (10 H, monosubstituted aromatic ring)] *dl*-IIIb [mp 136–140°,  $\lambda_{\text{max}}^{\text{EtOH}}$  281 m $\mu$  ( $\epsilon$  3200), nmr signals at  $\tau$  7.43 (3 H, NCH<sub>3</sub>), 6.15, 6.47 (6 H, two OCH<sub>3</sub>), 5.18 (2 H, two OH), 4.23 (1 H, C-8 H), 3.11, 3.29 (4 H, two doublets,  $J$  = 8.5 cps)] differed from that of phenol A. Hence phenol A was assumed to have the 4',5-diphenol structure IIIc, and thalidasine, an unprecedented diphenyl ether terminus at C-5. Evidence for both structures was adduced from the experimental results which follow.

Characterization of the *minor* phenolic products of reduction with sodium in liquid ammonia and mass spectroscopic evidence<sup>10</sup> strongly support assignment of structure Ia for thalidasine. One minor phenolic cleavage product was L-armepavine (IIIe), [ $\alpha$ ]<sub>D</sub><sup>20</sup> +99° (c 0.14, CHCl<sub>3</sub>), infrared and nmr spectra superimposable with those of authentic sample.<sup>13</sup> A second minor phenolic product was L-1-(4-methoxybenzyl)-2-methyl-6,7-dimethoxy-8-hydroxy-1,2,3,4-tetrahydroisoquinoline (IIb), [ $\alpha$ ]<sub>D</sub><sup>20</sup> +32° (c 0.40, CHCl<sub>3</sub>), infrared and nmr spectra superimposable with those of a sample of *dl* compound.<sup>14</sup> The most intense peak in the mass spectrum of thalidasine is a doubly charged ion (IV) of  $m/e$  213 (C<sub>24</sub>H<sub>30</sub>N<sub>2</sub>O<sub>6</sub>). This type of fragmentation has been shown to be characteristic of alkaloids of the unsymmetrical bisbenzylisoquinoline type.<sup>15,16</sup> Fragments with compositions C<sub>27</sub>H<sub>29</sub>NO<sub>4</sub>, C<sub>18</sub>H<sub>14</sub>O<sub>2</sub>, C<sub>14</sub>H<sub>11</sub>O<sub>2</sub>, C<sub>12</sub>H<sub>16</sub>NO<sub>3</sub>, and C<sub>12</sub>H<sub>16</sub>NO<sub>3</sub>, are readily explicable on the basis of structure Ia.

Thalfoetidine's chemistry supports the structural features assumed earlier,<sup>9</sup> apart from the termini of the diphenyl ether linkage. Methylation of thalfoetidine with diazomethane yielded O-methylthalfoetidine,<sup>9,16</sup> and direct comparison (infrared, nmr) has established the identity of the methylation product with thalidasine. Hence thalfoetidine possesses structure Ib.

## Photochemical and Base-Catalyzed Rearrangements of Isoxazolidines

Sir:

Intra-<sup>1</sup> and intermolecular<sup>2</sup> cycloadditions of nitrones and olefins have provided a new method for the formation of carbon-carbon bonds. Adaptation of this reaction as a synthetic method of broadest possible scope has stimulated investigations of the chemistry of the product isoxazolidine ring system. It is the purpose of this report to disclose our discovery of a rearrangement of N-alkylisoxazolidines to tetrahydro-1,3-oxa-

zines, an isomerization that can be effected both by ultraviolet irradiation and by strong base.

Irradiation of the fused bicyclic isoxazolidine 1a ( $\lambda_{\text{isoxazolidine}}^{\text{max}}$  213 m $\mu$  ( $\epsilon$  1940)) in hexane solution (0.027 M) with 2537-A light<sup>3</sup> afforded a product mixture from which the bicyclic tetrahydro-1,3-oxazine 2a could be isolated. Minor amounts of the amide 3 were also obtained, and the identity of 3 was established by synthesis from citronellic acid. The photochemical conversion of 1a to 2a could be efficiently photosensitized by the use of benzophenone and fluorenone (anthracene,  $E_T$  ~ 42 kcal/mole, proved to be a poor sensitizer). Under these conditions, the yields of 2a were 43 and 54%, respectively, and no amide 3 was detected. Similarly, isoxazolidine 1b was photoisomerized to 2b.

The structures of 2a and 2b were supported by their nmr spectra, which for the former showed an AB quartet at 4.25 ppm (2 H,  $J_{AB}$  = 10.5 cps), whereas 2b showed a regular quartet at 4.35 ppm (1 H,  $J$  = 5.6 cps). Reduction of each with lithium aluminum hydride produced the known<sup>1</sup> secondary amino alcohols 4, R = CH<sub>3</sub>, and 4, R = C<sub>2</sub>H<sub>5</sub>, respectively.

When 1a and 1b were heated with 0.5 equiv of potassium t-butoxide in DMSO for 5 hr at ~80°, the tetrahydro-1,3-oxazines were again obtained in good yield.

We propose that these reactions are mechanistically similar in that the imino alcohol 5 is a common intermediate. Cyclization of  $\gamma$ -hydroxy imines to tetrahydro-1,3-oxazines is well established.<sup>4</sup> For the photochemical transformation, energy transfer from triplet

sensitizer to give the excited triplet of 1 followed by bond cleavage would result in the diradical 6. Intramolecular hydrogen transfer *via* a seven-membered transition state leads directly to 5. Because 6 is a *t*-alkoxy radical, competing fragmentation could occur. In support of this postulated mechanism, we have succeeded in trapping acetone (as the 2,4-DNP) by sweeping the reaction mixture with nitrogen. The newly generated diradical 7 would be expected to rearrange to an imine (8), and 3-methylcyclohexanone was characterized after work-up with aqueous acid.<sup>5</sup>

Production of 5 in the base-promoted rearrangements can take place *via*  $\beta$  elimination. Direct evidence for the occurrence of this pathway in the reaction of 1c and *t*-butoxide has been obtained by isolation of imino alcohol 5c. When the reaction mixture was quenched by pouring into water, the primary amino alcohol 4 (R = H) was obtained; however, if sufficient acid was present to neutralize the base, both 4 (R = H) and 5c were detected. The isopropylideneimine 5c was synthesized by condensation of 4 (R = H) with acetone. Presumably 5c does not cyclize readily to a tetrahydro-1,3-oxazine because of steric hindrance.

Other polycyclic isoxazolidines have been subjected to these rearrangement conditions, and studies to define the limitations of such reactions are in progress.

**Acknowledgment.** This work was supported by a grant from the National Science Foundation.

(5) An alternate pathway to acetone and 8 is also possible: intramolecular hydrogen transfer involving a five-membered ring to give i which could undergo a retroaldol reaction.

## A Novel Photoinduced Ring Expansion of *1-t*-Butyl-2-phenyl-3-benzoylazetidine<sup>1</sup>

Sir:

As part of our broad interest in the ground-state and electronically excited-state behavior of small-membered rings,<sup>2</sup> we have investigated the photochemical behavior of *cis*-1-*t*-butyl-2-phenyl-3-benzoylazetidine<sup>3</sup> (I) and wish to describe an unusual photoinduced ring expansion of the four-membered azetidine ring. To our knowledge this represents the first example of a photochemical migration of an alkyl group from the  $\alpha$  position to the carbonyl carbon of an  $n-\pi^*$  excited state.

The initial experiments were carried out in a nitrogen atmosphere using an internal water-cooled mercury arc

lamp (Hanovia Type L, 450 w) with a Pyrex filter to eliminate wavelengths below 300 m $\mu$ . In a typical case a solution of 0.5 g of I in 150 ml of 95% ethanol was flushed with nitrogen and irradiated for 3 hr. Conventional isolation procedures afforded 0.46 g of a solid (95%), mp 102–103°, whose structure is assigned as 1-*t*-butyl-2,4-diphenylpyrrole (II) on the basis of the chemical and physical data cited. The infrared spec-

trum of II was characterized by a series of sharp bands at 6.24, 8.21, 12.47, 13.08, 13.50, 14.25, and 14.40  $\mu$ . The ultraviolet spectrum ( $\lambda_{\max}$  (95% alcohol) 235 m $\mu$  ( $\epsilon$  15,800) and 276 m $\mu$  ( $\epsilon$  16,200)) of II shows an absorption curve very similar to 2,4-diphenylfuran, with peaks occurring at approximately the same wavelengths ( $\lambda_{\max}$  (95% alcohol) 242 m $\mu$  ( $\epsilon$  19,400) and 277 m $\mu$  ( $\epsilon$  20,000)).<sup>5</sup> The nmr spectrum in deuteriochloroform exhibits a singlet at  $\tau$  8.60, a pair of doublets at  $\tau$  3.80 and 2.96 ( $J$  = 1.9 cps), and a multiplet centered at  $\tau$  2.62. The peak areas are in the ratio of 9:1:1:10. The doublet pattern of the 3- and 5-protons is to be expected, as it has been shown that the cross-ring or *meta* coupling constant ( $J_{3,5}$ ) in the pyrrole system has a value of approximately 2 cps.<sup>6</sup> The elemental analysis of this component (Anal. Calcd for C<sub>20</sub>H<sub>21</sub>N: C, 87.22; H, 7.69; N, 5.09. Found: C, 87.20; H, 7.85; N, 5.09) is also consistent with structure II. Chemical confirmation was obtained by pyrolysis of II at 225°. The product obtained in better than 97% yield was identical with an authentic sample of 2,4-diphenylpyrrole (III) synthesized by the method of Allen and Wilson.<sup>7</sup> Structure II was further confirmed by its unequivocal synthesis from 1,3-diphenyl-4-bromobuten-2-one-1 (IV) and *t*-butylamine.

(7) C. F. H. Allen and C. V. Wilson, "Organic Syntheses," Coll. Vol. III, John Wiley and Sons, Inc., New York, N. Y., 1955, p 348.

The mechanism by which I undergoes rearrangement and the identification of the excited state(s) responsible for the reaction were deemed of considerable interest. That the  $n-\pi^*$  singlet configuration is first populated and is the lowest energy state of this multiplicity seems to be a valid assumption since the absorption spectrum of I showed the  $n-\pi^*$  band at 320  $m\mu$ , whereas the  $\pi-\pi^*$  transition is at 246  $m\mu$ .<sup>8,9</sup> The nature of the lowest lying triplet configuration remains somewhat questionable at this time, although in the present instance the benzoyl group is involved, and the lowest triplet configuration of such a moiety is  $n-\pi^*$ . The quantum yield for formation of II in 95% ethanol is 0.046 at 3660 Å.<sup>10</sup> In an attempt to determine the rate constant for the unimolecular rearrangement of the excited state, we have studied the variation of quantum yield *vs.* quencher concentration. Surprisingly, the photolysis of I could not be quenched by a moderate concentration (0.3 mole) of perylene, 1,3-cyclohexadiene, naphthalene, or ferric dipivaloylmethide. The failure to quench could mean that the rearrangement of the  $n-\pi^*$  triplet is too rapid for diffusion of the excited state to quencher molecules or that most of the reaction proceeds from the singlet manifold.

With acetophenone present in a concentration so as to absorb 99% of the light a twofold increase in quantum yield resulted, despite the negligible direct excitation of azetidine I. The observation that the same product was obtained in the sensitized photolysis as in the direct irradiation provides proof that the azetidine triplet can rearrange to pyrrole II. Since the quantum yield of II increases by sensitization, we can conclude that either the intersystem crossing efficiency of the  $n-\pi^*$  singlet is low or the rate of crossing in this case may be much slower than in benzophenone or acetophenone, thereby allowing for a competing unimolecular rearrangement.<sup>11</sup> The increased quantum yield can also be equally well explained by reaction *via* singlets in the direct irradiation which is less efficient than reaction *via* triplets in the sensitized reaction, both configurations leading to the same product.

These results are consistent with a picture involving reaction of the  $n-\pi^*$  state as depicted in terms of the ensuing mechanism.

A possible explanation for the exclusive formation of the 2,4 isomer may be related to the preferred migratory aptitude of methyl *vs.* benzyl toward an electron-deficient center.<sup>14</sup> In view of the uncertainties in the electronic nature of the carbonyl carbon atom, we prefer to postpone further discussion of the reaction mechanism until a more thorough study can be undertaken.

(8) Pyrex filters were used in all irradiations to remove all light below 300  $m\mu$ .

(9) Irradiation of alcohol solutions of I with 2537-Å light so as to populate the  $\pi-\pi^*$  manifold produced 2,4-diphenylpyrrole. The effect of different wavelengths of light on I and the photochemistry of the *trans* isomer will be the subject of a future publication.

(10) Quantum yield measurements were carried out on a rotating photochemical assembly in sealed degassed Pyrex ampoules. Irradiation from a 450-w Hanovia lamp was filtered through Corning 7-51 filters. All the light is taken up by I under these conditions.

(11) A similar situation has been noted in the photochemistry of dibenzoylethylene, although in that case reaction proceeded predominantly by way of a  $n-\pi^*$  singlet.<sup>13,12</sup>

## Racemization, Ring Opening, and Ring Expansion of the [2.2]Paracyclophane Nucleus through a Diradical Intermediate<sup>1</sup>

Sir:

The smallest of the  $[m.n]$ paracyclophanes in which  $m = n = 2$  (I) exhibits a strain energy of 31.3 kcal/mole<sup>2a</sup> which is reflected in the highly deformed crystal structure of the molecule.<sup>2b</sup> The photochemical ring opening of [2.2]paracyclophane by both heterolytic and homolytic cleavage of the benzyl-benzyl bond results in release of this compression energy.<sup>3</sup> The thermal ring opening of the substance at 400° to give *p,p'*-dimethylbibenzyl and *p,p'*-dimethylstilbene<sup>4</sup> and at 600° to give *p*-xylylene<sup>5</sup> (II) also reflect the innate instability of the system. Octamethyl[2.2]paracyclophane is much more thermally unstable, a property attributed to diradical formation followed by polymerization.<sup>6</sup>

We wish to report the results of three types of experiments, all of which point to thermal cleavage of [2.2]paracyclophane to the *p,p'*-dimethylenebibenzyl diradical (III) whose fate depends on the medium.

When 40 mg of (–)-4-carbomethoxy[2.2]paracyclophane<sup>7</sup> (IV), mp 174–175°,  $[\alpha]_D^{25} -583^\circ$  (c 1, chloro-

(6) D. T. Longone and L. H. Simanyi, *J. Org. Chem.*, **29**, 3245 (1964).

(7) (a) Elemental analyses, nmr, and infrared spectra of all new compounds were in accord with the assigned structures. (b) Optically pure (–)-4-carboxy[2.2]paracyclophane [D. J. Cram and N. L. Allinger, *J. Am. Chem. Soc.*, **77**, 6289 (1955)] was previously reported.

form here and elsewhere), was heated in 0.96 g of dimethyl sulfone for 13.3 hr at 200°, 33 mg of ester with  $[\alpha]^{25}_{435} -77.5^\circ$  (13% optically pure) was isolated after purification by column chromatography and sublimation. A reaction conducted under identical conditions in *n*-tridecane gave 33 mg of material,  $[\alpha]^{25}_{435} -32.5^\circ$  (5.6% optically pure). The ratio of one-point first-order rate constants calculated from these data is  $k_{DS}/k_{TD} = 0.7$ . The constrictions of the ring system of IV preclude racemization as occurring by a path which does not involve ring cleavage. The insensitivity of the rate to solvent polarity suggests either the derived *p*-xylylene (carbomethoxy derivative of II) or diradical<sup>3</sup> (carbomethoxy derivative V) rather than a zwitterion as a reaction intermediate in the racemization.

When 1.0 g of [2.2]paracyclophane (I) was heated at 250° in 30 ml of *p*-diisopropylbenzene, 211 mg (21% yield) of *p,p'*-dimethylbibenzyl (mp 81–82°, undepressed by admixture with an authentic sample<sup>3</sup>) was isolated by column chromatography. This product suggested that diradical III intervened as the intermediate in this reduction, and that V was the intermediate in the above racemization reaction.

Dimethyl maleate and dimethyl fumarate esters exhibit particularly favorable tendencies to form ABAB copolymers in styrene radical polymerization under conditions that produce little homopolymerization.<sup>8</sup> Thus, it seemed possible that if diradical III were an intermediate in the thermolysis of I, then I might ring expand to a diester of [2.4]paracyclophane (VI) or VII) when heated with either of the two esters. Accordingly, 3.0 g of I was heated in 8.0 g of dimethyl fumarate in the absence of air at 200° for 40 hr. The product was subjected to silica gel chromatography and fractional crystallization; 0.902 g of starting material (I) was recovered, and 0.867 g of VI (mp 202.5–203.5°)<sup>7a</sup> and 0.800 g of VII (mp 88–89°)<sup>7a</sup> were isolated. A parallel experiment conducted in dimethyl maleate gave similar results.

(8) (a) C. Walling, "Free Radicals in Solution," John Wiley and Sons, Inc., New York, N. Y., 1957, p 132; (b) F. R. Mayo and C. Walling, *Chem. Rev.*, **46**, 191 (1950).

(9) These yields were determined by a combination of gravimetric and nmr procedures.

The nmr spectra of VI and VII exhibit high-field aromatic absorption bands (above  $\tau$  3.3) characteristic of the smaller [*m,n*]paracyclophanes.<sup>10</sup> The ultraviolet spectra of VI and VII are similar to that of [2.4]paracyclophane but distinctly different from other [*m,n*]paracyclophanes and open-chain materials.<sup>11</sup> Both VI and VII have carbonyl absorptions at 5.79  $\mu$  in their infrared spectra. Unambiguous proof that VI and VII possess the indicated ring structure is provided by degradation experiments. The diacid VIII<sup>7a</sup> derived from either VI or VII by alkaline hydrolysis was decarboxylated<sup>12</sup> with lead tetraacetate and lithium chloride in pyridine to give a 15–35% yield of dichloride IX,<sup>7a</sup> mp 147–148°. Treatment of IX with lithium in refluxing *t*-butyl alcohol–tetrahydrofuran<sup>13</sup> gave a 57% yield of [2.4]paracyclophane (X), identical with authentic material<sup>11a</sup> (melting point, mixture melting point, and nmr comparisons).

The assignment of the *trans* structure to VI and the *cis* structure to VII was made as follows. Treatment of VII with sodium methoxide in refluxing methanol–dimethoxyethane gave a high yield of VI (less than 0.5% of VII by nmr analysis remained). Thus, VI is more thermodynamically stable than VII by at least 3.5 kcal/mole. Molecular models indicate unambiguously that the *cis* structure is highly compressed compared to the *trans*. The rigid geometry of the ring system forces one of the carbomethoxy groups between the two benzene rings in the *cis* isomer.

Alkaline hydrolysis of either VI or VII gave the same diacid, VIII, which when reesterified gave only VI. Apparently VII isomerized during hydrolysis. Diacid VIII, when heated in acetic anhydride, readily formed the stable cyclic anhydride XI,<sup>7a</sup> 87% yield, mp 234.5–235.5°, carbonyl frequencies at 5.37 and 5.62  $\mu$  in the infrared. A sample of XI was hydrolyzed 25% in benzene with brucine hydrate at 80° for 20 min. The recovered anhydride gave  $[\alpha]^{25}_{435} 0.67^\circ$  (c 8, dichloromethane). The diacid formed was reconverted to anhydride, which had  $[\alpha]^{25}_{435} -2.68^\circ$  (c 8, dichloromethane). These experiments demonstrate unambiguously that XI, VIII, and VI possess the *trans* structures and are racemates, and that VII has the *cis* structure and is a *meso* form.

The olefin insertion reaction undoubtedly involves production of the diradical III, one benzyl carbon atom of which adds to olefin to produce a second diradical, XII, which in turn ring closes to give VI and VII. Intermediate XII must have a sufficient lifetime to destroy the stereochemical memory of the adding olefin before ring closure. The lack of stereospecificity<sup>14</sup> of the insertion reaction precludes any concerted addition to the diradical III or to [2.2]paracyclophane itself.

(14) Appropriate control experiments demonstrated that dimethyl maleate, dimethyl fumarate, and VII are essentially configurationally stable under the reaction conditions.

## Stereospecific Rearrangements in the Homocubyl Cation

Sir:

Of the fluconal molecules now known, bullvalene remains the most remarkable in that *via* a series of Cope rearrangements the system can undergo degenerate valence tautomerism which ultimately leads to complete scrambling of the carbon atoms in the framework.<sup>1</sup> Among other systems which can, in principle, behave similarly is the 9-homocubyl cation I; in this case, a succession of Wagner-Meerwein rearrangements continually regenerates the 9-homocubyl

cation and results in scrambling of the nine methine units.

In a recent communication, Schleyer and co-workers<sup>2</sup> have reported preliminary studies dealing with the synthesis and rearrangement of the homocubyl cation.

(1) W. von E. Doering and W. Roth, *Tetrahedron*, **19**, 715 (1963); G. Schröder, J. F. M. Oth, and R. Merenyi, *Angew. Chem. Intern. Ed. Engl.*, **4**, 752 (1965).

(2) P. von R. Schleyer, J. J. Harper, G. L. Dunn, V. J. Di Pasquo, and J. R. E. Hoover, *J. Am. Chem. Soc.*, **89**, 698 (1967).

We have independently been investigating this same problem and wish to report our initial results at this time. These results, based upon both a different synthesis and method of rearrangement detection, are in agreement with those of Schleyer, *et al.*,<sup>2</sup> in showing that the homocubyl cation when generated in acetic acid does undergo several degenerate rearrangements before forming the acetate. In addition, evidence indicates the reaction to be stereospecific and that much of the scrambling proceeds *via* internal return of the tosylate employed.

9-Homocubyl tosylate was prepared by two related pathways. Oxidative decomposition of cyclobutadieneiron tricarbonyl with lead tetraacetate in pyridine in the presence of cyclopentadienone diethyl ketal<sup>3</sup> afforded the adduct II.<sup>4</sup> In path a irradiation of II in acetone gave 9,9-diethoxyhomocubane which upon

hydrolysis yielded homocubanol III. Reduction of III with sodium borohydride produced 9-homocubanol which was converted to the tosylate in the usual manner. The tosylate (mp 73–73.5°) displayed absorptions in the nmr at  $\tau$  2.42 (area 4), 5.12 (1), 6.33–7.00 (8), and 7.56 (3).<sup>6</sup> In path b, hydrolysis of the ketal II followed by reduction with NaBH<sub>4</sub> afforded predominantly the alcohol IV in which the stereochemistry of the hydroxyl group is as indicated.<sup>7</sup> Irradiation of IV gave homocubanol.

(3) P. E. Eaton and R. A. Hudson, *ibid.*, **87**, 2769 (1965).

(4) Decomposition with ceric ion<sup>5</sup> was unsatisfactory in that the ketal was rapidly hydrolyzed and dimerized to dicyclopentadienone.

(5) J. C. Barborak, L. Watts, and R. Pettit, *J. Am. Chem. Soc.*, **88**, 1328 (1966).

(6) The physical properties of 9-homocubanol and its acetate and tosylate were identical with those reported by Schleyer and co-workers.<sup>1</sup>

(7) This isomer is formed in better than 90% yield. The stereochemistry is indicated by the nmr pattern of the 7,8-olefinic protons (triplet) characteristic of 7-antibrominated norbornenes [see E. I. Snyder and B. Franzus, *J. Am. Chem. Soc.*, **86**, 1166 (1964)]. In addition, in the mixture of tetradeuterated 9-homocubyl tosylates made *via* pathway a (see text) there exists two distinct regions of absorptions for the ring protons other than C<sub>9</sub>; these occur in the regions  $\tau$  6.4–6.6 and 6.6–7.0 of areas 1:3, respectively. The lower field set ( $\tau$  6.4–6.6) must therefore be associated with those protons situated beneath the tosylate group rather than those  $\beta$  to the tosylate group. In the *d*<sub>4</sub> tosylate made *via* path b there is no absorption in the region  $\tau$  6.4–6.6 but all four protons appear at  $\tau$  6.65–6.9; therefore, the tosylate must be *syn* to two deuterium atoms, which requires the stereochemistry shown in IV.

In order to follow the extent of possible rearrangement of the homocubyl ion accompanying solvolysis, the tetradeuterio derivative of homocubanol was prepared in an analogous manner starting with perdeuterio-cyclobutadieneiron tricarbonyl.<sup>8</sup> Path a afforded an equal mixture of the two tosylates V and VI, while path b afforded the single isomer V.

A sample of V and another consisting of an equal mixture of V + VI was solvolysed in acetic acid at 120° for 30 hr, and the acetates and unreacted tosylates were recovered.<sup>10</sup> The unique chemical shift of the C<sub>9</sub> proton in both the acetate and the tosylate allows a direct measure of the extent of rearrangement; however, the amount of deuterium appearing at C<sub>9</sub> will also depend on the stereospecificity of the process. In a stereospecific process involving repeated migration of the carbon atom *trans* to the leaving group, the sample of V should show twice as much deuterium at C<sub>9</sub> as that of the mixture V + VI since VI in such a process cannot generate deuterium at C<sub>9</sub>. However, in a nonstereospecific process, the two samples should produce the same amount of deuterium at C<sub>9</sub>.

The acetate produced from V showed 26.1 ± 3% deuterium at C<sub>9</sub>, while that from V + VI showed 12.3 ± 3%. The scrambling process under these conditions is clearly stereoselective if not entirely stereospecific. The relationship between the number of rearrangements which occur and the amount of deuterium they generate at C<sub>9</sub> for the stereospecific process is shown in Table I.<sup>11</sup>

Table I. Percentage of D at C<sub>9</sub> Accompanying 1,2 Shifts of V

No. of 1,2 shifts	0	1	2	3	4	5	6	∞
% D at C <sub>9</sub>	0	0	12.5	21.9	28.1	32.2	35.0	40.0

On the average close to four Wagner-Meerwein shifts had therefore occurred in the over-all solvolysis. The recovered tosylates also contained deuterium at C<sub>9</sub> and to a larger degree than that observed for the acetates;<sup>12</sup> again approximately twice as much deuterium appeared at C<sub>9</sub> in the reaction of V as with the mixture V + VI. This indicated stereospecific rearrangement *via* internal return of the tosylate ion pair.<sup>13</sup> The results of Schleyer and co-workers, however,

(8) Prepared by repeated treatment of cyclobutadieneiron tricarbonyl with CF<sub>3</sub>COOD.<sup>9</sup> Analysis by nmr methods indicated the starting perdeuterio complex contained at least 98% deuterium.

(9) J. D. Fitzpatrick, L. Watts, G. F. Emerson, and R. Pettit, *J. Am. Chem. Soc.*, **87**, 3254 (1965).

(10) Under these conditions approximately 80% of the tosylate had reacted. The acetates were purified by repeated crystallization from pentane (mp 10–12°).

(11) This table ignores the isotope effect.

(12) Greater than five shifts are indicated.

(13) Concerning the question of possible bridged ion intermediates, it is of interest to note the stereospecificity of these rearrangements together with the enhanced rate of acetolysis found by Schleyer and co-workers.<sup>2</sup>

clearly indicate that in formolysis, at least, stereochemical leakage can occur.<sup>2</sup>

## Cycloaddition Reaction of a Triafulvene with Enamines. Intermediacy of a 5-Methylenebicyclo[2.1.0]pentane

Sir:

Our recent study of the reaction of diphenylcyclopropenone with enamines<sup>1,2</sup> prompted our investigation of the electronically similar triafulvene I.

Addition of 1.03 mmoles of freshly distilled 1-diethylamino-1,3-butadiene (II)<sup>3</sup> in 3 ml of anhydrous benzene to 0.928 mmole of 1,2-diphenyl-3-dicyanomethylenecyclopropene (I)<sup>4</sup> in 7 ml of benzene under a nitrogen atmosphere followed by heating at 50–60° for 2 hr produced a deep red color. Dilution with methylene chloride, extraction with aqueous 5% hydrochloric acid and saturated sodium chloride, removal of solvent, and recrystallization from benzene-hexane afforded brilliant orange needles in 82% yield, mp 200.5–201.0°. Structure IV is assigned on the basis of the following data:  $\nu_{\text{max}}^{\text{CHCl}_3}$  (cm<sup>-1</sup>) 2215 (s),

1610 (s), 1555 (m), 1450 (s), 1415 (s), 1350 (m);  $\lambda_{\text{max}}^{\text{C}_2\text{H}_5\text{OH}}$  (m $\mu$ ) 493 ( $\epsilon$  92,500), 247 (13,100), ~290 (5520); nmr (CDCl<sub>3</sub>) (ppm from TMS) 1.05 (6 H, triplet,  $J$  = 7

cps), 3.11 (4 H, quartet,  $J = 7$  cps), 4.97 ( $H_B$ , triplet,  $J_{AB} = J_{BC} = 12$  cps), 5.43 ( $H_D$  or  $H_E$ , singlet,  $J_{DE} = 0$ ), 6.00 ( $H_B$  or  $H_D$ , singlet,  $J_{BD} = 0$ ), 6.76 ( $H_C$ , doublet,  $J_{CB} = 12$  cps), 7.13–7.60 (11 H, complex multiplet, aromatics and  $H_A$ ).<sup>5</sup> *Anal.* Calcd for  $C_{26}H_{23}N_3$ : C, 82.29; H, 6.64; N, 11.07; mol wt, 379. Found: C, 82.41; H, 6.87; N, 11.04; (mass spectrum)  $m/e$  379.

Tetraene IV<sup>6</sup> must arise from an initial 1,2 cycloaddition of the 3,4-double bond of II<sup>7</sup> to the endocyclic double bond of I<sup>8</sup> and subsequent ring opening of the bicyclic intermediate III.<sup>9</sup>

Reaction of 0.723 mmole of 1-(N-pyrrolidino)-2-methylpropene (VI) with 0.618 mmole of I in benzene under similar conditions produced triene VIII as yellow plates in 92% yield after similar work-up and recrystallization from benzene-hexane: mp 188–189°;  $\nu_{\text{max}}^{\text{CHCl}_3}$  ( $\text{cm}^{-1}$ ) 2210 (s), 1585 (s), 1455 (s), 1390 (s), 1310 (s);

$\lambda_{\text{C}_2\text{H}_5\text{OH}}^{\text{max}}$  (m $\mu$ ) 403 ( $\epsilon$  43,300), 236 (15,200), 290 (sh) (3600); nmr ( $\text{CDCl}_3$ ) (ppm from TMS) 1.5–1.8 (4

(5) The nmr spectra were recorded with a Varian A-60-A spectrometer. Mass spectral data were recorded on a Hitachi RMU-6D spectrometer. The infrared and ultraviolet data were taken on a Perkin-Elmer Model 337 grating spectrophotometer and a Cary Model 14 spectrophotometer, respectively. The A-60-A and RMU-6D spectrometers were purchased through a National Science Foundation major equipment grant to Brown University.

(6) Examination of Dreiding models reveals that the tetraene probably possesses the more favorable *trans,trans* geometry.

(7) The cycloaddition of sulfene ( $\text{CH}_2=\text{SO}_2$ ) proceeds by initial attack at the 3,4-double bond of 1-dialkylamino-1,3-butadienes [G. Opitz and F. Schweinsberg, *Angew. Chem.*, **77**, 811 (1965); Leo A. Paquette, private communication]. Ketene, on the other hand, undergoes cycloaddition to the 1,2-double bond of 1-(2-ethyl-4-methyl-1,3-pentadien-1-yl)piperidine [R. H. Hasek, P. G. Gott, and J. C. Martin, *J. Org. Chem.*, **31**, 1931 (1966)].

(8) The addition of 1-diethylamino-1,3-butadiene to a dibenzocyclohexene derivative proceeds in 1,4 manner [H. Prinzbach, U. Fischer, and R. Cruse, *Angew. Chem.*, **78**, 268 (1966)].

(9) The simplicity of the nmr spectrum precludes the alternative possibility of an initial cycloaddition of I to the 1,2-double bond of II to give ultimately, after ring opening, tetraene V.

H,  $-\text{CH}_2\text{CH}_2-$ , multiplet), 1.88 (3 H,  $\text{CH}_3-$ , singlet), 1.98 (3 H,  $\text{CH}_3-$ , singlet), 2.7–3.3 (4 H,  $-\text{CH}_2\text{NCH}_2-$ , broad singlet), 7.05–7.40 (10 H, multiplet, aromatics), 7.56 (vinyl H, singlet). *Anal.* Calcd for  $C_{26}H_{23}N_3$ : C, 82.29; H, 6.64; N, 11.07; mol wt, 379. Found: C, 82.29; H, 6.86; N, 11.09; (mass spectrum)  $m/e$  379.

The production of compounds IV and VIII necessitates the intermediacy of the substituted 5-methylenebicyclo[2.1.0]pentane derivatives III and VII,<sup>10</sup> respectively. Whether the formation as well as the ring opening of intermediates III and VII proceeds by a concerted or stepwise process is questionable.

Further investigations of these reactions employing other enamines as well as triafulvenes are in progress.

**Acknowledgment.** We thank the National Institutes of Health (Grant No. GM 14579-01) for generous support of this work.

(10) The reaction of 1,2-diphenyl-3-carbomethoxymethylenecyclopropane with tetracyanoethylene reportedly proceeds across the exocyclic double bond of the triafulvene to give a spirohexene derivative [M. A. Battiste, *J. Am. Chem. Soc.*, **86**, 942 (1964)]. On the other hand, 1,2-di-*n*-propyl-3-dicyanomethylenecyclopropane fails to react with tetracyanoethylene under similar conditions [A. S. Kende and P. T. Izzo, *ibid.*, **86**, 3587 (1964)].

## Catalysis of Hydrogen Exchange in *m*-Dinitrobenzene<sup>1</sup>

Sir:

In the interaction of aromatic nitro compounds with bases, nuclear hydrogen abstraction is the least well characterized process; the formation of charge-transfer complexes,<sup>2a</sup> of radical anions,<sup>2b</sup> and latterly of Meisenheimer adducts<sup>3</sup> is well substantiated. Due to the contradictory reports<sup>4–10</sup> as to the feasibility and significance of such proton abstraction we have undertaken a systematic study of the process. Further, it was hoped that these studies would also provide information on the nature of the catalysis of aromatic hydrogen abstraction. Whereas general-base catalysis of proton abstraction from aliphatic carbon (eq 1) is well documented,<sup>11a</sup> corresponding evidence for

aromatic hydrogen has not yet been available. The reason is clearly that abstraction of aromatic hydrogen, conveniently measured by isotopic exchange, typically

$\text{Y}^-$  = a Brønsted base  
 $\text{X}$  =  $-\text{CO}-$ ,  $-\text{NO}_2$ ,  $-\text{CF}_3$ , etc.

requires very strongly basic systems such as potassium amide in liquid ammonia<sup>12</sup> or lithium cyclohexylamide in cyclohexylamine;<sup>13</sup> these systems have afforded valuable information on relative acidities of hydrogens in different environments but have left unanswered the question whether Brønsted bases such as azide ion, amines, etc., can partake in aromatic hydrogen abstraction.

The compound chosen for study was 1,3-dinitrobenzene since this was reported<sup>7</sup> to exchange the 2-hydrogen under the unusually mild conditions of sodium deuterioxide in DMF- $\text{D}_2\text{O}$ . We now report some results of the effect of a number of Brønsted bases, and also of reaction medium, on this hydrogen-exchange process. The media examined were dimethylformamide, dimethyl sulfoxide, and dimethoxyethane, containing deuterium oxide. Exchange was allowed to proceed at 30° for the more reactive bases and at 100° for the less reactive ones. The extent of exchange under standard conditions is taken to be a measure of the relative proton abstracting abilities of the bases in the particular media.

The results (Table I) indicate a dependence of reactivity on medium and base. The effect of medium is seen with reference to deuterioxide,<sup>14</sup> acetate, and azide ions. The DMF and DMSO media are about equally facile in base catalysis and are much more effective than DME. In considering a reactivity order with respect to base the anionic and neutral bases must be treated separately to allow for the markedly different medium effects on base strength expected for bases of different charge type;<sup>15</sup> the basicity of the anionic bases will be greatly enhanced by a change to a dipolar aprotic medium, but the basicity of the neutral bases will remain relatively unaffected.<sup>16</sup> Among the anionic bases the reactivity order, for DMF medium, is  $\text{DO}^- > \text{PhO}^- > \text{SO}_3^{2-} \approx \text{AcO}^- > \text{N}_3^-$ , which approximates a decreasing order of base strength as given by the  $\text{pK}_a$ 's of the conjugate acids.<sup>17</sup> The

data for the amines do not fall into a definite order, consistent with the known<sup>11b,18</sup> medium dependence of relative base strengths of primary, secondary, and tertiary amines. Pyridine is seen to be unreactive.

Table I. Exchange of the 2-Hydrogen in 1,3-Dinitrobenzene<sup>a</sup>

$\text{Y}^-$ (pK <sub>a</sub> ) <sup>c</sup>	Medium <sup>d</sup>	Temp, °C	% deuteration <sup>e</sup>

Pyridine (5.4)	DMF	100	0

<sup>a</sup> Reaction time was 16 hr throughout. <sup>b</sup> The anions were present as sodium salts. Concentrations were:  $[\text{Y}^-] = 0.05 \text{ M}$ ; [dinitrobenzene] = 0.5 M. In the case of the phenoxide exchange 0.05 M phenol was also present, to repress the deuterioxide ion concentration. <sup>c</sup> The  $\text{pK}_a$  values refer to water. <sup>d</sup> Contains 10%  $\text{D}_2\text{O}$  by volume. <sup>e</sup> Exchange was measured by infrared and nmr; no evidence was found for exchange of the other hydrogens of the substrate. Maximum theoretical deuteration with the experimental D:H ratio was 95%.

A number of factors are pertinent in consideration of the above results. (1) The apparent parallelism between the extent of exchange and  $\text{pK}$  is not alone conclusive evidence of Brønsted base catalysis, since lyate ion catalysis as the main cause of exchange is not ruled out thereby. In this respect the significantly lower reactivity of triethylamine, particularly in comparison with the unhindered tertiary amine 1,4-diazabicyclo[2.2.2]octane, which can be ascribed to steric hindrance to proton transfer,<sup>19</sup> argues against lyate ion catalysis as the predominant factor. (2) Evidence has been presented<sup>20</sup> that, as a result of hydrogen bonding, internal return in the solvated carbanions may form part of the rate-determining step in certain reaction media. In this connection it is noted that the DMF- $\text{D}_2\text{O}$  medium was used in a similar study<sup>21</sup> of kinetic acidities of some carbon acids and that the derived  $\text{pK}_a$  scale was in good accord with data obtained from other studies.<sup>22</sup> Hence the common mechanism for these exchange processes is taken to be rate-determining

for bases of a given charge type.<sup>11,16</sup> (Sulfite ion should, strictly, not be included in the series for this reason.)

(13) A. Streitwieser, Jr., J. R. Caldwell, R. G. Lawler, and G. R. Ziegler, *ibid.*, **87**, 5399 (1965).

(14) DMSO medium was not used in the case of deuterioxide since DMSO itself undergoes a facile deuterioxide-catalyzed hydrogen exchange.<sup>16</sup> No evidence was found for hydrogen exchange of DMSO in presence of azide or acetate ions.

(15) E. Buncl, E. A. Symons, and A. W. Zabel, *Chem. Commun.*, 173 (1965).

(16) A. J. Parker, *Quart. Rev. (London)*, **16**, 163 (1962); B. W. Clare, D. Cook, E. C. F. Ko, Y. C. Mac, and A. J. Parker, *J. Am. Chem. Soc.*, **88**, 1911 (1966); R. G. Pearson, *ibid.*, **85**, 3533 (1963); R. Gompper, *Angew. Chem. Intern. Ed. Engl.*, **3**, 560 (1964).

(17) The  $\text{pK}_a$  values quoted are for  $\text{H}_2\text{O}$ ; they will be affected by a change to  $\text{D}_2\text{O}$  and also to the largely nonaqueous media. Considerations of the  $\text{pK}$  dependence of hydrogen exchange will be valid as long as the relative order of the  $\text{pK}$ 's remains unaffected by the medium changes. There is good ground for the general validity of this assumption.

ing abstraction of hydrogen by the Brønsted base, followed by fast protonation by solvent of the resulting carbanion (eq 2-4). (3) Since the reaction medium

in some of these exchange processes ( $\text{Y}^- = \text{OD}^-$ ,  $\text{PhO}^-$ ,  $\text{S}_2\text{O}_3^{2-}$ ) was strongly colored (deep red or purple) it is possible that the anion was partly tied up in the form of Meisenheimer adducts; on the other hand the colors may only be indicative of charge-transfer complexing. Detailed equilibrium studies with respect to complex formation, coupled with kinetic studies on the exchange process, will be required to separate these effects. The studies relevant to these factors are under active consideration.

## Epoxyamines. A New Functional Group in Organic Chemistry

Sir:

We wish to report the preparation and rearrangement of a new class of organic compounds, the epoxyamines. Although the concept of this unusual functional group has been invoked as an intermediate in several instances,<sup>1-3</sup> isolation and complete characterization of an example previously had not been accomplished.<sup>4</sup> The apparent inaccessibility of these compounds had been attributed to their high reactivity and to the possibility of facile rearrangements.<sup>1,2</sup>

We have now isolated a stable crystalline epoxyamine, 2-(1-aziridinyl)-2-phenyl-1-oxaspiro[2.5]octane (2), by the action of the lithium salt of ethylenimine<sup>5</sup>

(1) C. L. Stevens, P. Blumbergs, and M. Munk, *J. Org. Chem.*, **28**, 331 (1963), and references cited therein.

(2) A. Kirmann and H. I. Joschek, *Bull. Soc. Chim. France*, 3483 (1963).

(3) A. Hassner and P. Catsolacos, *J. Org. Chem.*, **32**, 549 (1967).

(4) M. Mousseron, J. Jullien, and Y. Jolchine, *Bull. Soc. Chim. France*, 757 (1952), reported the formation of an epoxyamine as a by-product in the reaction of 2-chlorocyclohexanone with aqueous dimethylamine, but they did not fully characterize or establish the structure of the material.

(5) The fact that ethylenimine forms stable addition products with

on  $\alpha$ -bromocyclohexyl phenyl ketone<sup>6</sup> (1) in ether at room temperature. Evaporative distillation (bath temperature 90–100° (0.01 mm)) of the crude product gave 70–75% of 2, bp 90–95° (0.001 mm),  $n_D^{25}$  1.5870, which could be crystallized from pentane; mp 20–22°. The infrared spectrum was devoid of any hydroxyl and carbonyl absorptions but had strong peaks at 1025 and 1045  $\text{cm}^{-1}$ . The nmr spectrum ( $\text{CDCl}_3$ ) was consistent with structure 2, showing aromatic protons from  $\tau$  2.45 to 2.85 and aliphatic protons from  $\tau$  7.8 to 9.0 in the ratio 5:14.

Hydrolysis with 2 *N* hydrochloric acid converted 2 into the known  $\alpha$ -hydroxycyclohexyl phenyl ketone<sup>6</sup> (3) in 90% yield. Reduction of 2 with sodium borohydride in methanol gave 1-[ $\alpha$ -(1-aziridinyl)benzyl]cyclohexanol (4) (60%), mp 113–114°. Hydrogenation of 4 in ethanol at atmospheric pressure using 10% palladium on carbon as catalyst yielded 1-( $\alpha$ -*N*-ethylaminobenzyl)cyclohexanol (5), characterized as its hydrochloride (85%), mp 223–224° dec. This amino alcohol 5 was also formed in 80% yield by direct hydrogenation of 2 in methanol using the same catalyst. The structure of 5 was confirmed by its formation from the sodium borohydride reduction of  $\alpha$ -hydroxycyclohexyl phenyl ketone *N*-ethylimine, which in turn was made from ethylamine and 3 in the presence of potassium carbonate.

When heated to the reflux temperature in *o*-dichlorobenzene for 15 hr under a nitrogen atmosphere, 2 rearranged with ring expansion to give 2-(1-aziridinyl)-2-phenylcycloheptanone (6) in 35–38% yield, the remainder of the material being an intractable resin. This rearrangement was particularly interesting, since according to a previous postulate<sup>7</sup>  $\alpha$ -(1-aziridinyl)cyclohexyl phenyl ketone (7) would have been the expected product. To show that 7 was not an intermediate in the transformation of 2 to 6, 7 was prepared by the general method<sup>8</sup> involving the action of ethyl-

aldehydes and ketones suggested that it might impart stability to this class of compounds. Cf. A. Dornow and W. Schacht, *Chem. Ber.*, **82**, 464 (1949).

(6) C. L. Stevens and E. Farkas, *J. Am. Chem. Soc.*, **74**, 618 (1952).

(7) A. Kirmann, R. Mutha, and J.-J. Riehl, *Bull. Soc. Chim. France*, 1469 (1958).

(8) C. L. Stevens and C. H. Chang, *J. Org. Chem.*, **27**, 4392 (1962).

on an epoxy ether, 2-methoxy-2-phenyl-1-epoxy[2.5]octane,<sup>6</sup> in 84% yield (bp 102–105° mm),  $n_D^{25}$ , 1.5502). After 7 was subjected to the rearrangement conditions, most of the starting material (55%) was recovered unchanged and an examination of the infrared spectrum of the crude reaction provided evidence that no detectable amount of 6 was formed.

Upon hydrogenation in ethyl acetate at atmospheric pressure in the presence of 10% palladium on carbon, 6 was selectively reduced to 2-N-ethylamino-2-phenylcycloheptanone (8), characterized as its hydrochloride (85%), mp 233–235° dec,  $pK_a' = 7.70$  (50% methanol). Ketone 8 was converted to the corresponding oxime 9 (64%), mp 105–106°,  $pK_a' = 8.75$  (50% methanol). Synthesis of 9 was also achieved by the action of ethylamine on the known 2-chloro-2-phenylcycloheptanone oxime<sup>9</sup> (12). Structure 9 was further confirmed by the formation of 6-benzoylhexanamide (10) (60%), mp 107–108°, when the oxime was subjected to Beckmann degradation conditions using polyphosphoric acid. On treatment with aqueous alcoholic sodium hydroxide 10 was hydrolyzed to the known 6-benzoylhexanoic acid (11) (90%), mp 82–83°. The identity of 11 was established by mixture melting point determination with an authentic sample.

All new numbered compounds have analyses and spectral data consistent with their structures.

## Additions and Corrections

**Analysis of  $\alpha$ -Hydrogen Exchange. I. The Reaction of n-Butyraldehyde-2-d with Tertiary Amines and Acid Bases** [*J. Am. Chem. Soc.*, **87**, 5050 (1965)]. BY JACK HINE, JAMES G. HOUSTON, JAMES H. JENSEN, JULIEN MULDER, School of Chemistry, Georgia Institute of Technology, Atlanta, Georgia.

In this paper an incorrect value for the van der Waals constant of argon was used. The distance 2.45 Å, at which the energy of repulsion is 11.2 kcal/mole, is of 2 times 1.91 Å, the atomic radius for argon as given by G. Pannetier, "Nouveau Traité de Chimie Minérale," P. Pascal, Ed., Vol. 1, Masson et Cie., 1956, p 941. With this change, eq 2 becomes

$$E_r = 0.112 \left( \frac{d_0}{d} \right)^{11} - 0.175 \left( \frac{d_0}{d} \right)^7 + 0.06 \quad (2)$$

The energies of repulsion (calculated without allowance for molecular distortion) are only 32% as large as

those calculated originally, but they are still considerably larger than the experimental values. None of the qualitative conclusions is affected by this change.

**A Molecular Orbital Theory of Optical Rotatory Strengths of Molecules** [*J. Am. Chem. Soc.*, **88**, 4157 (1966)]. By YOH-HAN PAO and D. P. SANTRY, Bell Telephone Laboratories, Inc., Murray Hill, New Jersey, and Carnegie Institute of Technology, Pittsburgh, Pennsylvania.

On page 4158, eq 1.2 should read

$$\psi_i = \sum_{\mu} \chi_{\mu} C_{\mu i} \quad (1.2)$$

On page 4159, line 10 of column 1 should read  $M$  is the magnetic moment operator. Equation 2.9 should read

$$\langle \psi_j | \mathbf{m} | \psi_i \rangle = -i \sum_{\mathbf{A}} [(C_{zA_j} C_{xA_i} - C_{xA_j} C_{zA_i}) \mathbf{x} + (C_{yA_j} C_{yA_i} - C_{yA_j} C_{yA_i}) \mathbf{y} + (C_{zA_j} C_{zA_i} - C_{zA_j} C_{zA_i}) \mathbf{z}] \times \mathbf{R}_A W_{sp}^A + (C_{yA_j} C_{zA_i} - C_{zA_j} C_{yA_i}) \mathbf{x} + (C_{zA_j} C_{xA_i} - C_{xA_j} C_{zA_i}) \mathbf{y} + (C_{xA_j} C_{yA_i} - C_{yA_j} C_{xA_i}) \mathbf{z}] \quad (2.9)$$

On page 4161, second column, the first sentence should read: The equatorial proton of carbon atom 2 lies in a negative octant, and almost in the plane *B*. The octant rule predicts a small negative rotation for  $H_7$  in methylcyclohexanone. On page 4162, line 5 of column 1, delete the words "shown in Figure 3."

**Stereochemical Consequences of Methoxyl Participation. The Stereochemistry of the Cyclization of 5-Methoxy-2-pentyl Brosylate to 2-Methyltetrahydrofuran** [*J. Am. Chem. Soc.*, **89**, 73 (1967)]. By ERNEST R. NOVAK and D. STANLEY TARBELL, Department of Chemistry, University of Rochester, Rochester New York 14627.

Add the following sentence to the last paragraph in the second column on page 74: If this assignment of configuration is correct, the  $[+]$ -2-chloro-5-methoxypentane is formed from the (*R*)-brosylate **3b** by a process involving *one* inversion. On page 76, revise the last sentence of the first paragraph under Discussion of Results to read as follows: Attack of chloride ion at C-5 of the methoxonium ion yields the 5-chloro-2-methoxypentane, the latter with (*R*) configuration, because removal of the chlorine yields (*R*)-2-methoxypentane.

**A New and Convenient Alkylation and Acylation of Pyridine N-Oxides** [*J. Am. Chem. Soc.*, **89**, 1537 (1967)]. By R. A. ABRAMOVITCH, MAITREYI SAHA, and ELIZABETH M. SMITH, University of Saskatchewan, Saskatoon, Saskatchewan, Canada, and R. T. COUTTS, University of Alberta, Edmonton, Alberta, Canada.

On page 1538, the structures just above the Acknowledgment should be numbered VII.

## Book Reviews

**The Chemistry of Technetium and Rhenium.** By R. D. PEACOCK, Professor of Inorganic Chemistry, The University of Leicester, Great Britain. American Elsevier Publishing Co., Inc., 52 Vanderbilt Ave., New York, N. Y. 1966. 137 pp. 14 X 22 cm. \$10.00.

Although one book and six review articles on one or the other of the elements technetium and rhenium have appeared during the period 1957-1964, a critical discussion and comparison of the chemistry of these two metals, last published in one volume 10 years ago (in French), is now most welcome. Despite the rarity of these two elements (technetium has only recently become available in weighable quantities at a price of about \$200/g), there have been over 500 citations in the literature about them and interest is increasing. This no doubt is due in part to the chemical novelties discovered through this group such as the first demonstration of Lewis base properties for a transition metal in its complexes (in the reaction  $(C_6H_5)_3ReH + H^+ \rightarrow (C_6H_5)_3ReH_2^+$ ), the unique ions  $TcH_2^{2-}$  and  $ReH_2^{2-}$  containing only transition metal to hydrogen bonds, the polynuclear halogenometalate  $Re_2Cl_3^{2-}$  whose diamagnetism can best be explained by a quadruple bond between rhenium atoms, and the first polynuclear carbonyl hydrides,  $H_2Tc(CO)_{12}$ ,  $H_2Re(CO)_{12}$ , and  $HRe(CO)_{14}$ . (The latter was characterized too recently to be included in this monograph; another recent discovery in this group is the rare trigonal prismatic coordination for  $Re(S_2C_2Ph)_2$ , the first known molecular complex to display this geometry.)

In the present monograph the literature is well covered through 1963 with some references to later work appearing in scattered portions of the text. A general bibliography and further references (through June 1965) are presented in two appendices which will be useful to the reader. The first two chapters in the text deal with the discovery, isolation, and general properties of the two elements. A systematic survey is presented in the next eight chapters, under the following headings: Oxides; Oxoacids and Oxosalts; Halides and Oxide Halides; Complex Halides, Complex Oxide Halides and Complex Hydrides; Chalcogenides and Compounds with Nonmetals and Metalloids, Alloys; Complex Cyanides and Related Compounds; Carbonyls and Organometallic Derivatives; Compounds with Group V and Group VI Ligands. Seven figures are scattered throughout these chapters summarizing related chemical

reactions in a schematic way; these will also be a help to the reader. A chapter on analytical methods and three appendices (two mentioned above and one containing notes on the laboratory handling of technetium) conclude the text. A subject but no author index is available.

In the area of organometallic chemistry and polynuclear carbonyl hydrides, the coverage of the literature was incomplete, and the cited references suffered from more than the average typographical errors. Furthermore this reviewer takes issue with the heading " $M-C^*$ ," first column of infrared frequencies in Table 28 (p 105). These are alleged to have been assigned by the original workers to the M-H frequency. In the first place, no such assignment was proposed by those authors, but even so the substitute chosen for it is little better. In all likelihood the absorptions in question are mixtures of the several characteristic modes, the M-CO and M-H deformation as well as the M-C stretching vibrations, which fall in this range of energy.

The discussions of many subjects are extremely brief, and only a moderate number of tables of data are supplied. I do not believe a specialist would find this book useful as a desk copy. However, for others it should be valuable as an introduction to the literature. In this respect it is only somewhat more up to date than a monograph on precisely the same subject matter (by R. Colton) which was published a short time before (in a competing series on inorganic chemistry from Interscience). Such duplication is wasteful and of no advantage to the scientific community. The present divided and competing efforts are even more regrettable since they come from two former coauthors (R. Colton and R. D. Peacock, "The Chemistry of Technetium," *Quart. Rev. (London)*, **16**, 311 (1962)). There ought to be some mechanism either between publishers or between authors to combine such efforts for the benefit of the readers and produce one work of greater scope and usefulness; for the present, at least one of these two monographs should find a place in any library specializing in chemistry.

**ness of Chemicals on Dividing Cells.** By BENGT A. KIHLMAN, dr. Swedish Natural Science Research Council, Research Program of Biochemical Cytogenetics, Institute of Physiological Botany, Uppsala, Sweden. Prentice-Hall, Inc., Englewood Cliffs, N. J. 1966. xi + 260 pp. 16 × 23 cm. \$10.00.

The molecular mechanisms by which genes mutate have come to be fairly well understood in recent years. Since many of the physical and chemical agents that induce gene mutation also cause chromosome breakage and rearrangement, there has been reason to hope that our knowledge of these latter phenomena would advance rapidly. Moreover, in understanding what it takes to break and reorganize chromosomes, one could also expect to learn a good deal about chromosome structure and replication. Unfortunately, however, as this book makes abundantly clear, the problems of chromosome organization and breakage have not led to analysis as swiftly as have the analogous ones of gene structure and mutagenesis. Although a satisfactory explanation of the effects of chemical agents on chromosomes is not yet available, Professor Kihlman has performed a great service in condensing and arranging all of the relevant facts. His book will certainly be read with profit by students of the chromosome for many years to come.

Professor Kihlman has not been afraid to confront experimental facts that are contradictory or difficult to reconcile or out of line with attractively plausible hypotheses. While many knotty questions are left open, the author manages to keep our attention and to avoid confusion. The first part of the book is a brief review of the histology and physiology of the interphase cell, of DNA synthesis, chromosome replication, and mitosis. This review serves as a useful background for the second part, which is devoted to the inhibition of mitosis and the production of chromosomal aberrations by chemical agents. A critical assessment of the experimental findings leaves us with little doubt that most of these agents affect either the structure or synthesis of DNA, but a clear relation between primary action of a chemical agent and a specific aberration cannot be unequivocally discerned. Nevertheless, we may hope that Professor Kihlman that "once fundamental chromosome structure is understood, the damaging effect of chemicals will be more readily comprehensible, and all of the pieces of the puzzle will then fall into place." In the meantime, this book provides a useful summary of what we know and what we need to know.

**Stable Monolayers at Liquid-Gas Interfaces.** By GEORGE L. NILES, JR., Research Laboratory, General Electric Co., Schenectady, N. Y. Research Division of John Wiley and Sons, Inc., 605 Third Ave., New York, N. Y. 1966. viii + 386 pp. 15.5 × 23 cm. \$14.00.

A half-century ago Irving Langmuir, one of the true geniuses in American chemistry, invented the surface balance and initiated systematic investigations on the properties of insoluble films on aqueous sub-solutions. Not only did he confirm the speculation of Lord Rayleigh and Agnes Pockels that these films were truly molecular, but he also discovered that the molecules in them are oriented with their polar groups immersed in the water and their long, nonpolar chains directed nearly vertically up from the surface. During the first 25 years after Langmuir's first publication, there was much activity in the United States and elsewhere, and the discipline of surface chemistry became firmly established. In the period following World War II, however, there seemed to be a slackening of interest until quite recently when the advance of monolayers to the control of evaporation from water reservoirs and to the understanding of the structures of membranes in living systems was recognized. This renaissance of research activity on insoluble monolayers is accurately reflected by this important new monograph; its appearance is timely and it is likely to stimulate further the realization of the elegance of the experimental method and its promise for understanding intermolecular forces.

The monograph has been written primarily for the researcher who wishes to study unimolecular films either for their own sake or to gain an understanding of natural phenomena involving liquid interfaces and oriented molecules. The tone of the book is essentially descriptive and critical with emphasis on modern

experimental methods and data with a minimum of interpretation. The coverage of laboratory procedures and techniques is comprehensive, and detailed accounts are given of the methods for measuring surface pressures, areas, contact potentials, and viscosities. The applications of optical and related methods, of radioactive tracers, and of measurements of gas transport and evaporation in the elucidation of monolayer behavior are also treated.

The organization and scope of the treatment is revealed by the thoughtfully chosen titles of the nine chapters of the book: Historical Introduction, The Properties of Liquid Surfaces, Experimental Methods: Properties of Liquid Surfaces, Experimental Methods: Properties of Monolayer Films, The Properties of Various Substances in Mono-molecular Films, Mixed Monolayers, Reactions in Monolayers, Transfer of Monolayers to Solids, and Scientific and Technological Applications. The usefulness of the work is augmented by its subject and author indexes and particularly by its index of film-forming compounds. The style of writing is graceful, clear, and concise when appropriate. The author, himself an active research worker on monolayers, is to be congratulated for his scholarly effort in getting out this highly useful, up-to-date summary.

Because of the detailed, almost handbook character of the long discussion (105 pages) on experimental methods, it was surprising that nothing seems to be said about methods for purifying the film-forming compounds themselves or about criteria for their purity. Dramatic examples of the importance of this factor may be found in the discrepancies reported in the literature between experienced investigators. Gas chromatographic techniques in their preparative and analytical applications should do much to ensure that highly accurate measurements will not be performed on impure compounds. Yet, this apparent omission is surely minor compared to the over-all usefulness of the book, which is recommended strongly for the beginner as well as for the experienced investigator.

**Recent Developments in the Chemistry of Natural Carbon Compounds. Volume I.** By G. FODOR, D.Sc., Member of the Hungarian Academy of Sciences, Stereochemical Research Laboratory, Hungarian Academy of Sciences, K. NADOR, D.Sc., Institute for Experimental Medicine, Hungarian Academy of Sciences, and I. V. TORGOV, D.Sc., Institute of Organic Natural Compounds, Academy of Sciences of the USSR. Akadémiai Kiadó, Publishing House of the Hungarian Academy of Sciences, Budapest, Hungary. 1965. 319 pp. 17 × 24 cm. \$16.50.

This book is Volume 1 in a series, "Recent Developments in the Chemistry of Natural Carbon Compounds," the individual feature of which will be to collect "for the first time the relevant work of Hungarian chemists which so far has been available only scattered throughout the pages of various journals."

This first volume contains three sections, the first two of which are clearly directed toward the goal of making the results of Hungarian chemical research more readily available. G. Fodor, late of the Stereochemical Research Laboratory of the Hungarian Academy of Sciences and presently of Laval University, Quebec, Canada, writes on "New Methods and Recent Developments of the Stereochemistry of Ephedrine, Pyrrolizidine, Granatane and Tropane Alkaloids," with particular emphasis on work done in Hungary, though the entire field is very extensively reviewed. Most of the Hungarian work has used chemical interrelations between appropriate substances; modern physical techniques have not played a major role. A significant amount of work on biosynthesis of these alkaloids is also reviewed.

The second section, on "Relationships between the Structure and Pharmacological Activity of Tropeines" by K. Nador of the Institute of Experimental Medicine, also of the Hungarian Academy of Sciences, is an appropriate companion to the first. Nador, likewise, stresses the work in Hungary on this problem, particularly his own work and hypotheses. A large number of tables summarize the semiquantitative aspects of work in this area.

I. V. Torgov, of the Institute of Organic Natural Compounds of the Academy of Sciences of the USSR, has contributed the third section on "Achievements in the Total Synthesis of Natural Steroids," which, in a very different vein from the first two sections, reviews very concisely the work from the early synthesis of equilenin by Bachman, Cole, and Wilds in 1939-1940 to the synthesis of the

cardiac aglycone, digitoxigenin, and the steroidal alkaloid, conessine, in 1962. In the 84 pages of this section, Torgov has effectively outlined the many milestones in steroid synthesis. Because the literature is not reviewed beyond 1962, neither Barton's retraction of his first report on the synthesis of conessine nor Stork's synthesis of this substance are mentioned. Much of the material in this section is available already in L. F. Fieser's "Steroids," though the conciseness of Torgov's treatment and the importance of the subject make this the most generally interesting section of the book.

The text contains many instances of grammatical constructions unknown to Fowler, though the meaning is seldom, for this reason, unclear. The present volume can be recommended for those interested in the Hungarian work on stereochemistry and pharmacological activity of a family of alkaloids or in a concise review of steroid synthesis. The book suffers, badly, however, from the absence of either a subject or an author index.

In the Rayonet® RPR-208 type RS Preparative Photochemical Reactor, for the first time, a commercial unit has been made available which can be readily used to irradiate even high-boiling organic compounds in the vapor phase. We firmly believe that a wealth of knowledge on photochemical reactions in the vapor phase now awaits the organic photochemist.

® TRADEMARK

## Methods in Preparative Organic Photochemistry No. 2

# Organic Synthesis via Vapor Phase Irradiations

In liquids and solutions excited electronic states of molecules invariably get deactivated to their zeroth vibrational level before any chemical reaction is observed. To accomplish any significant decomposition from higher vibrational levels of the excited electronic state, the irradiation has to be carried out in the vapor phase. A further advantage in vapor phase photoreactions is that unimolecular reactions of the excited molecule can compete successfully with bimolecular processes such as dimerization, abstraction and addition. Nevertheless, this procedure has held little appeal to organic chemists in view of the special equipment that is usually used in such experiments and also the small quantity of material that can be handled.

The RPR-208 reactor when used as shown in the adjoining figure allows a simple solution to the problem. The vertical cylinder is the irradiation cell which is placed at the center of the bank of 8 high-energy ultraviolet lamps. The flask contains the reactant which can be used as either a pure liquid if its b.p. is  $<180^\circ$  or as a solution in a solvent (that does not absorb the light) for higher boiling materials. The material should have a vapor pressure  $>1$  mm at the b.p. of the solvent. Any material that boils below  $200^\circ$  at 15 mm is a suitable reactant. The condenser returns the vapor to the flask and cycles the material. The heat from the lamp is usually sufficient to prevent condensation of the vapors on the wall of the cell. Many reac-

Two of the lamps and the framework of the reactor are not shown in this schematic representation.

tions which are known only in the gas phase are easy to carry out in this way.

The intense photon energy of the new Rayonet RPR-208 reactor makes it possible to handle quantities of material which would interest the synthetic organic chemist. The availability of three sets of light sources for the reactor extends this method to the whole near ultraviolet range from 200-450m $\mu$ .

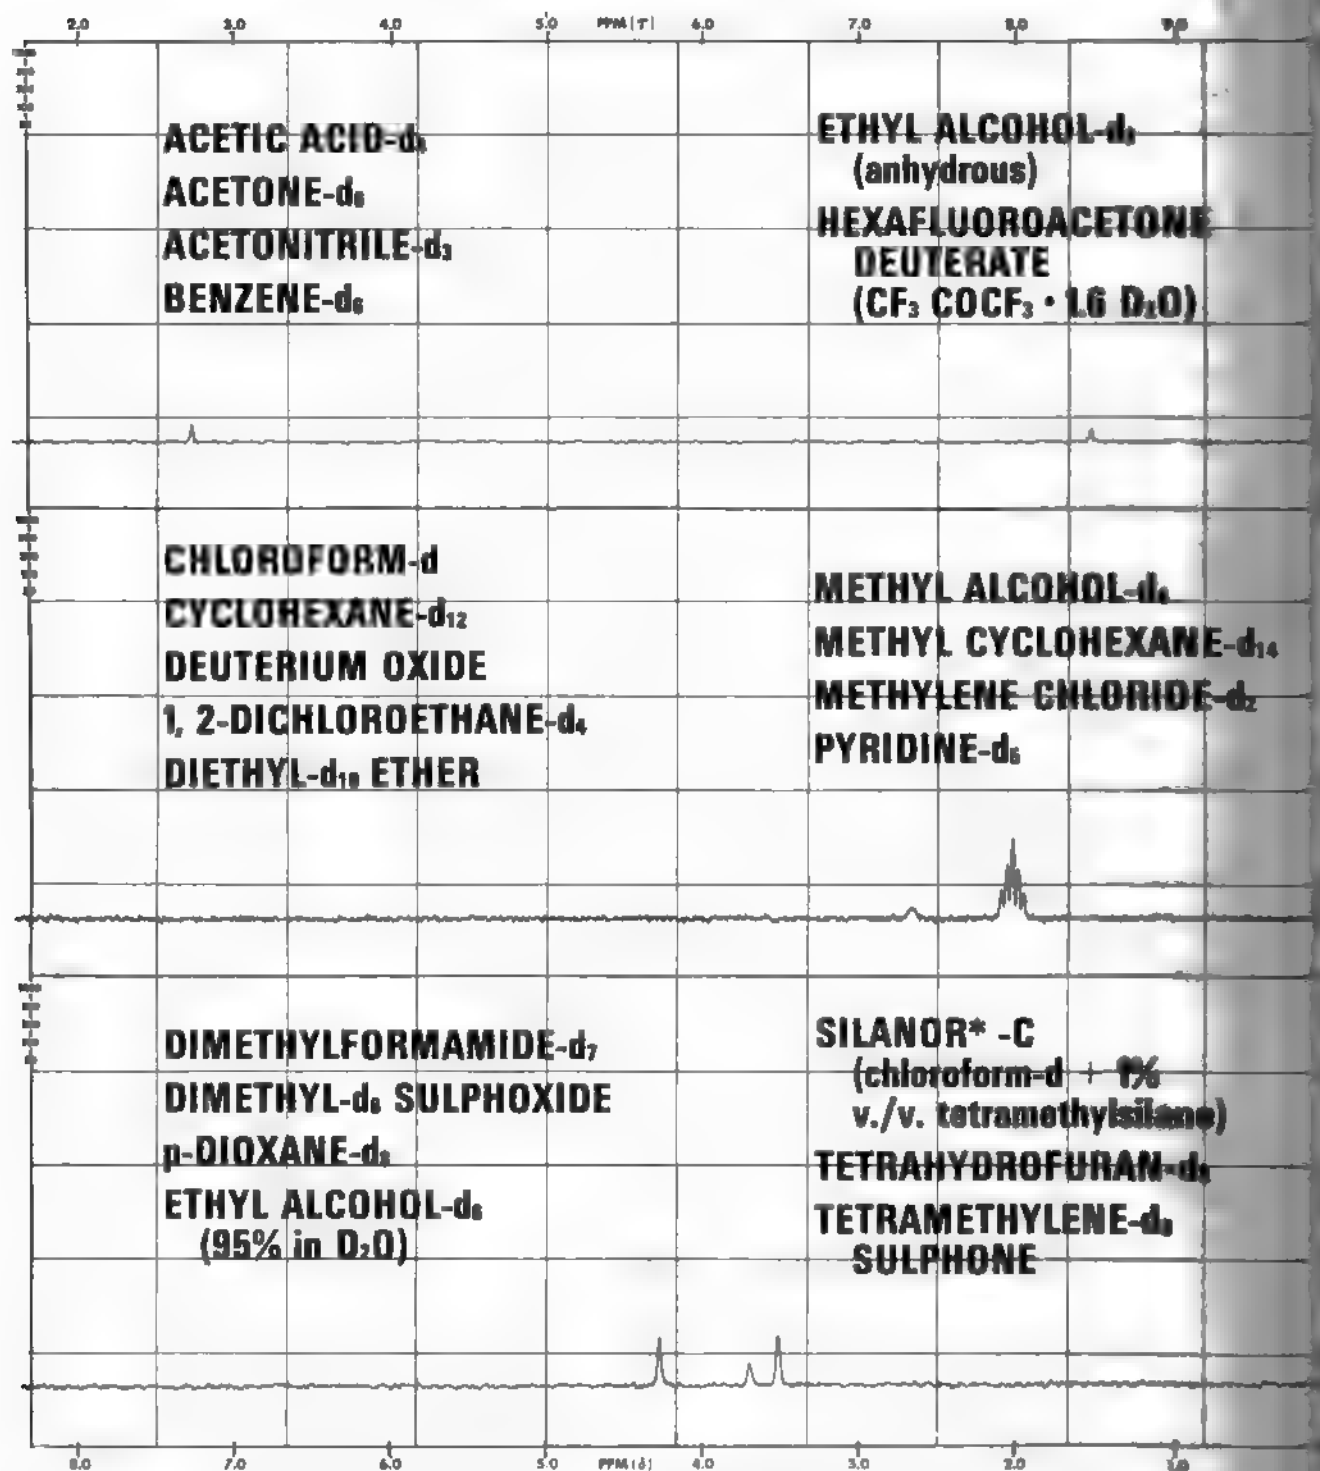

For more information about the Rayonet RPR-208 or the RPR-100 Reactor and interchangeable light sources, write to:

# Mass Spectrometry

## At Work No. 3

### Adjustable Slits

This series demonstrates some of the analytical capabilities of Varian's M-66 Mass Spectrometer—an advanced, medium resolution, double-focusing cycloidal instrument.

In mass spectrometry it is very desirable to be able to trade off resolution for sensitivity and vice versa. Usually one wants maximum sensitivity with resolution adequate to resolve adjacent mass peaks. This condition permits detection of very small samples and also permits the operator to use the lowest possible temperatures to volatilize sensitive compounds. On the other hand, improved resolution is often required in order to resolve mass doublets or to make accurate mass measurements. Several peaks in the spectrum of bromoform are shown above at a resolution of about 1400 and again at 4600.

This tradeoff between resolution and sensitivity by using variable slits is accomplished in the M-66 with a unique slit adjusting mechanism. Two controls on the operator console are for changing independently the source and collector slit widths and permit convenient, reproducible adjustment. The range of resolution available is approximately 1000 to 5000 ( $M/\Delta M_{1/2max}$ ).

Other subjects in this series will cover relation of instrument parameters to the data obtained, and instrument features which make the M-66 Mass Spectrometer a useful tool for chemical studies. Please address your comments or questions to: Varian, Mass Spectrometer Product Manager, Analytical Instrument Division, 611-C Hansen Way, Palo Alto, California.

## Physical and Inorganic Chemistry

### Ground States of $\sigma$ -Bonded Molecules. I. A Semiempirical SCF MO Treatment of Hydrocarbons<sup>1</sup>

Michael J. S. Dewar and Gilles Klopman<sup>2</sup>

*Contribution from the Department of Chemistry, The University of Texas,  
Austin, Texas 78712. Received January 28, 1967*

**Abstract:** In a recent series of papers<sup>3</sup> it was shown that the heats of formation of conjugated molecules can be calculated with surprising accuracy by the Pople SCF MO method, the  $\sigma$  bonds being treated as localized. Here we describe an extension of the method to include all the valence electrons in a molecule, using procedures similar to those suggested by Pople, Santry, and Segal<sup>4</sup> and by Klopman.<sup>5</sup> Preliminary calculations for a number of hydrocarbons are reported; the agreement between the calculated and observed heats of formation is already very satisfactory, implying that this approach should ultimately give results of sufficient accuracy to be of value in predicting the structures and reactivities of molecules.

In a recent series of papers<sup>3</sup> it was shown that the heats of formation from atoms of conjugated molecules can be calculated with quite unexpected accuracy ( $\pm 0.1\%$ ), using the localized bond model for the  $\sigma$  bonds and calculating the  $\pi$  binding energy by the Pople method. However, although this approach represents a very considerable advance over anything previously reported, it is still of limited chemical value; it cannot be applied to reactions even of conjugated molecules since transition states do not normally have the symmetry necessary for the  $\pi$  approximation to be applicable, nor can it be applied to many problems concerning the behavior of unconjugated molecules, e.g., conformational equilibria and steric hindrance.

However, in view of the unexpected success of the  $\pi$  calculations, it seems reasonable to hope that an

analogous treatment of  $\sigma$  bonds might prove equally successful; if so, we would have a complete solution of the basic problems of chemistry. Preliminary calculations of this kind for diatomic molecules have indeed proved very promising,<sup>5</sup> and Pople, Santry, and Segal<sup>4</sup> have reported preliminary calculations for larger molecules. Here we describe our own initial efforts in this direction, which already seem to have achieved a degree of accuracy almost in the "chemical" zone.

#### Theoretical Approach

The Pople SCF MO method is now familiar, and the problems involved in its extension to  $\sigma$ -bonded systems have been discussed in a formal manner by Pople, Santry, and Segal. The following pictorial representation has the advantage of clarifying these problems and will also help to illustrate our own approach.

In the original Pople treatment of conjugated systems, the  $\pi$  MOs  $\psi_\mu$  are written as linear combinations of p AO's  $\phi_i$  of the participating atoms (eq 1). The choice of

$$\psi_\mu = \sum_i a_{\mu i} \phi_i \quad (1)$$

basis set functions  $\phi_i$  is unambiguous, since the orientation of each  $\phi_i$  is determined by the geometry of the  $\pi$  system. In calculations for a three-dimensional,  $\sigma$ -bonded system, the situation is more complicated.

Figure 1. Illustrating the interactions between an electron in an s AO ( $\phi$ ) of atom N, and an electron in a p AO ( $\psi$ ) of atom M.

Each atom other than hydrogen will contribute at least three p AO's; the orientation of these orbitals is arbitrary, since there will normally be no reference frame to fix the choice of coordinate axes. Since the choice of axes is arbitrary, the results of the calculation must be independent of it. While this condition is automatically met in a complete Roothaan SCF MO treatment, the same is not necessarily the case in the simplified version of Pople. The following example illustrates the difficulty.

Consider the interactions between two electrons, one occupying an s AO ( $\phi$ ) of atom M, and the other, a p AO ( $\psi$ ) of atom N,  $\psi$  having its axis along the line joining the two nuclei (Figure 1a). In a coordinate system where this line is one of the coordinate axes,  $\psi$  will be represented as a single p AO. The terms in the total energy that represent the interactions between the two electrons are of two kinds; first there will be a one-electron resonance integral  $\beta$ , given by

$$\beta = \int \phi H^C \psi d\tau \quad (2)$$

where  $H^C$  is the core operator; secondly there will be an electron repulsion term  $\gamma$ , given by

$$\gamma = \iint \phi^2(1) \frac{e^2}{r_{12}} \psi^2(2) d\tau_1 d\tau_2 \equiv (\phi\phi, \psi\psi) \quad (3)$$

in the usual notation for such integrals.

Suppose now that we calculate these interactions in a coordinate system rotated through  $45^\circ$  about the  $z$  axis (Figure 1b). The AO  $\phi$  must now be written as a linear combination of the  $p_x$  AO ( $\xi$ ) and the  $p_y$  AO ( $\eta$ ); i.e.

$$\phi = \frac{1}{\sqrt{2}}(\xi + \eta) \quad (4)$$

The corresponding one- and two-electron interaction terms,  $\beta'$  and  $\gamma'$ , are then given by eq 5 and 6. If our

$$\beta' = \int \phi H^C \psi d\tau = \frac{1}{\sqrt{2}}(\int \xi H^C \psi d\tau + \int \eta H^C \psi d\tau) \quad (5)$$

$$\begin{aligned} \gamma' = \iint \phi^2(1) \frac{e^2}{r_{12}} \psi^2(2) d\tau_1 d\tau_2 = \\ \frac{1}{2} \iint \xi^2(1) \frac{e^2}{r_{12}} \psi^2(2) d\tau_1 d\tau_2 + \frac{1}{2} \iint \eta^2(1) \frac{e^2}{r_{12}} \psi^2(2) d\tau_1 d\tau_2 + \\ \iint \xi(1)\eta(1) \frac{e^2}{r_{12}} \psi^2(2) d\tau_1 d\tau_2 \equiv \frac{1}{2}[(\xi\xi, \psi\psi) + (\eta\eta, \psi\psi) + \\ 2(\xi\eta, \psi\psi)] \quad (6) \end{aligned}$$

calculation is to be independent of the choice of coordinate axes, it is necessary that

$$\beta \equiv \beta' \quad (7)$$

$$\gamma \equiv \gamma' \quad (8)$$

Equation 7 will be automatically satisfied if we make the usual assumption that one-electron resonance integrals are proportional to overlap integrals. The second condition will be met in a full Roothaan treatment where all electron repulsion integrals are included; however, in the standard Pople treatment, where integrals involving overlap between different AO's are neglected, complications will arise, since the final integral in eq 6 will be set equal to zero. Since the remaining integrals in eq 6 are equal, from symmetry, eq 8 will be satisfied only if

$$(\phi\phi, \psi\psi) = (\xi\xi, \psi\psi) = (\eta\eta, \psi\psi) \quad (9)$$

Since these integrals represent the mutual repulsions of two clouds of charge, one representing the distribution of an electron occupying a p AO, the other the distribution of an electron occupying an s AO, the condition implied in eq 8 is equivalent to the assumption that such clouds of charge are spherically symmetrical. This is the CNDO approximation of Pople, *et al.*<sup>4</sup> (complete neglect of differential overlap). In it one assumes that electron repulsion integrals of the type  $(\chi\chi, \omega\omega)$  depend on the nature of the orbitals  $\chi$  and  $\omega$  and on their distance apart, but not on their orientation.

Our experience indicates, however, that this approximation is too severe. In spite of very extensive trials, we have been unable to devise any satisfactory scheme for calculating heats of formation of molecules based on the CNDO approximation. This is not surprising, for the directivity of valence probably depends at least partly on the variation with orbital orientation of repulsion integrals involving p AO's. If so, one would not expect to be able to calculate heats of formation accurately, using an approximation in which these variations are neglected.

If such variations in the repulsion integrals are to be included in our treatment, we must then include three- and four-orbital repulsion integrals, involving overlap of orbitals on a common center. In other words, *all* two-center repulsion integrals must be included. We can still, of course, neglect three- and four-center integrals, involving overlap between AO's of different atoms, for neglect of these does not affect the invariance of our calculations to choice of coordinate axes. Thus in the notation of Figure 1, and with  $\chi$  representing an AO of a third atom, we can set

$$(\chi\phi, \psi\psi) = (\chi\xi, \psi\psi) = (\chi\eta, \psi\psi) = 0 \quad (10)$$

without affecting the invariance to rotation, for the contribution of such integrals will be zero no matter what axes we choose.

This is the NDDO approximation of Pople, *et al.*<sup>4</sup> (neglect of diatomic differential overlap); it involves obvious technical difficulties, and no calculations have as yet been reported in which the full NDDO scheme has been adopted. Not only are there a large number of additional integrals to be evaluated, but it is also difficult to estimate them by the kind of semiempirical approach we have used for the two-orbital integrals.<sup>1,2</sup> While the NDDO approximation may prove essential, and while we are at present developing an appropriate program for applying it, we decided first to try the following intermediate approximation in the hope that it might combine simplicity with adequate accuracy.

consider the integrals  $(km,ln)$  between AO's of two atoms M and N. First we transform the AO's of the molecule into the coordinate system of Figure 2. The repulsion integrals between the original AO's can then be expressed in terms of corresponding integrals between the transformed AO's. In this new system, three-orbital integrals involving overlap between any of p AO's vanish through symmetry, as also do the corresponding four-orbital integrals. We assume that the remaining three- and four-orbital integrals can be neglected. The neglect of integrals involving overlap between an s AO and p AO of a given atom can be shown to have no effect on the invariance of the calculations to choice of coordinate axes. The neglect of integrals involving four distinct p AO's can in principle affect this invariance; however, various experiments indicate that such effects are negligible (see *14*). With these assumptions our problem is greatly simplified, for the remaining two-center integrals are now of the standard two-orbital type, i.e.,  $(kk,ll)$ . This approach might be termed the PNDDO approximation (partial neglect of diatomic differential overlap). There are ten distinct integrals of this kind to be considered for the orbitals indicated in Figure 2, viz.

$$\begin{aligned} & s\sigma_N, s\sigma_M-p\sigma_N, p\sigma_M-s\sigma_N, p\sigma_M-p\sigma_N, s\sigma_M-p\pi_N, \\ & -s\sigma_N, p\pi_M-p\pi_N, p\sigma_M-p\pi_N, p\pi_M-p\sigma_N, p\pi_M-p\pi_N^* \end{aligned} \quad (11)$$

The last integral,  $p\pi_M-p\pi_N^*$ , is one between the  $p_y$  AO of M and the  $p_x$  AO of N, or conversely. For  $n$  atoms, there are therefore  $5n(n-1)$  different integrals; in our computer program, each set of integrals is stored in half of an  $n \times n$  matrix, five such matrices being required.

Our treatment also involves repulsion integrals between orbitals of a single center; here the three- and four-orbital integrals vanish through symmetry, only two-orbital integrals of the type  $(kk,mm)$  and  $(km,km)$  remain. Integrals of the latter type must be retained; otherwise we could not distinguish between singlet and triplet states of atoms; thus the difference in energy between the singlet and triplet configurations  $(1s)^2(2p)^2$  of carbon arises from an integral of this type where  $\phi_k$  and  $\phi_m$  are different 2p AO's.

We neglect inner electrons, e.g., the 1s electrons in carbon; we treat the valence electrons as moving in the field of a set of cores, each composed of a nucleus and of occupied inner AO's. Thus the core of carbon is a  $C^{4+}$ , consisting of the nucleus and a pair of electrons.

The one-center repulsion integrals  $(kk,mm)$  and  $(km,km)$  are estimated from spectroscopic data for the corresponding atom by a procedure considered in detail *15*. In this it is assumed that the repulsion between pairs of electrons in the valence shell of a given atom is a value independent of the orbitals occupied by the electrons and depending only on their relative spins,

$$\text{repulsion between electrons of like spin} = A_M^+ \quad (12)$$

$$\text{repulsion between electrons of opposite spin} = A_M^- \quad (13)$$

and the two-center repulsion integrals can be expressed in terms of

Figure 2. Illustrating calculation of electron repulsion integrals.

these quantities as

$$(kk,mm) = A_M^- \quad (k = m \text{ or } k \neq m) \quad (14)$$

$$(km,km) = A_M^- - A_M^+ \quad (k \neq m) \quad (15)$$

In order to make the treatment as general as possible, we derived an expression for the total electronic energy ( $E_{el}$ ) for an open-shell SCF MO treatment. Here  $q_i^\alpha, q_j^\beta$  are respectively the densities of  $\alpha$ -spin and  $\beta$ -spin electrons in the AO's  $\phi_i$  and  $\phi_j$ , given by

$$q_i^\alpha = \sum_\mu n_\mu^\alpha a_{\mu i}^2 \quad q_j^\beta = \sum_\nu n_\nu^\beta a_{\nu j}^2 \quad (16)$$

where  $n_\mu^\alpha$  and  $n_\mu^\beta$  are the numbers of electrons (zero or unity) occupying the corresponding MO's  $\psi_\mu^\alpha$  and  $\psi_\mu^\beta$ . Likewise  $p_{ij}^\alpha$  and  $p_{ij}^\beta$  are the corresponding bond orders, defined by eq 17. In the case of a closed-shell

$$\begin{aligned} p_{ij}^\alpha &= \sum_\mu n_\mu^\alpha a_{\mu i} a_{\mu j} \\ p_{ij}^\beta &= \sum_\nu n_\nu^\beta a_{\nu i} a_{\nu j} \end{aligned} \quad (17)$$

molecule, the net charge densities  $q_i$  and bond orders  $p_{ij}$  are given by

$$q_i = 2q_i^\alpha = 2q_i^\beta \quad p_{ij} = 2p_{ij}^\alpha = 2p_{ij}^\beta \quad (18)$$

The expression for  $E_{el}$  is shown in eq 19. Here

$$\begin{aligned} E_{el} = & \sum_k^{(M)} \left\{ (q_k^\alpha + q_k^\beta) W_k + \sum_m^{(M)} \left\{ \sum_{N \neq M} \left[ k_x m_x V_{kN}^\sigma + \right. \right. \right. \\ & (k_y m_y + k_z m_z) V_{kN}^\pi \left. \right] (p_{km}^\alpha + p_{km}^\beta) + \frac{1}{2} \left[ q_k^\alpha q_m^\alpha - (p_{km}^\alpha)^2 + \right. \\ & \left. q_k^\beta q_m^\beta - (p_{km}^\beta)^2 \right] A_M^+ + \frac{1}{2} (q_k^\alpha q_m^\beta + q_k^\beta q_m^\alpha) A_M^- \left. \right\} + \\ & \sum_k^{(M)} \sum_{l>k}^{(N)} \left\{ 2(p_{ki}^\alpha + p_{ki}^\beta) \left[ k_x l_x \beta_{ki}^\sigma + (k_y l_y + k_z l_z) \beta_{ki}^\pi \right] \right\} + \\ & \sum_m^{(M)} \sum_n^{(N)} \left\{ (p_{km}^\alpha p_{ln}^\alpha + p_{km}^\beta p_{ln}^\beta + p_{km}^\alpha p_{ln}^\beta + p_{km}^\beta p_{ln}^\alpha - \right. \\ & \left. p_{kn}^\alpha p_{lm}^\alpha - p_{kn}^\beta p_{lm}^\beta) \left[ k_x l_x m_x n_x \gamma_{kl}^{\sigma\sigma} + (k_y l_y m_y n_y + \right. \right. \\ & \left. \left. k_x l_x m_z n_z) \gamma_{kl}^{\sigma\pi} + k_x m_x (l_y n_y + l_z n_z) \gamma_{kl}^{\pi\sigma} + (k_y m_y + \right. \right. \\ & \left. \left. k_z m_z) l_x n_x \gamma_{kl}^{\pi\sigma} + (k_y m_y l_z n_z + k_z m_z l_y n_y) \gamma_{kl}^{\pi\pi} \right] \right\} \end{aligned} \quad (19)$$

$\phi_k$  and  $\phi_m$  are AO's of one atom M, while  $\phi_i$  and  $\phi_n$  are AO's of some other atom N; the summations are labeled accordingly to avoid confusion.

The integral  $W_k$  represents a sum of the kinetic energy of an electron occupying the AO  $\phi_k$  and its potential energy due to attractions by the core of the corresponding atom (M). The integrals  $V_{kN}^\sigma$  and  $V_{kN}^\pi$  represent respectively the attractions between an electron in a  $\sigma$ -type AO (s or  $p\sigma$ ) or a  $\pi$ -type AO,  $\phi_k$ , and the core of

atom N. The quantities  $A^+$  and  $A^-$  have already been defined (eq 14 and 15). The remaining one-electron integrals  $\beta_{ki}^r$  and  $\beta_{ki}^r$  are resonance integrals between AO's of atoms M and N in the local coordinate system of Figure 2. There are five nonvanishing combinations of this type, *i.e.*

$$s\sigma-s\sigma, s\sigma-p\sigma, p\sigma-s\sigma, p\pi-p\pi, p\sigma-p\sigma \quad (20)$$

where the first symbol designates the orbital  $\phi_k$ , the second  $\phi_i$ .

The quantities  $\gamma_{ki}$  are two-orbital repulsion integrals for orbitals of atoms M and N, again in the local coordinate system of Figure 2; *i.e.*

$$\gamma_{ki} \equiv (kk, ll) \quad (21)$$

The integrals are labeled with superscripts to indicate the types of orbital involved; the distinction between  $s\sigma$  and  $p\sigma$  types follows automatically from the nature of the AO's. Thus if  $\phi_k$  and  $\phi_m$  are p AO's, the integral  $\gamma_{ki}^{rr}$  is of the  $p\sigma$ - $p\pi$  type, while if  $k = m$  and  $\phi_k$  is a  $\sigma$  AO, the integral is of the  $s\sigma$ - $p\pi$  type. (Note that in our scheme  $\gamma_{ki}^{rr}$  vanishes if  $\phi_k$  is an s AO and  $k \neq m$ , since three- and four-orbital integrals involving s-p overlap are neglected.)

The quantities  $k_x, k_y, \dots, n_x$  are involved in the transformation of the original basis set of AO's into the locally oriented sets of Figure 2. They are defined in (22), where  $i = k, l, m$ , or  $n$ , and other terms are defined

	Type of orbital $\phi_i$			
	s	p <sub>x</sub>	p <sub>y</sub>	p <sub>z</sub>
$i_x =$	1	X	Y	Z
$i_y =$	0	$-rY/R$	$rX/R$	0
$i_z =$	0	$-rXZ/R$	$-rYZ/R$	$R/r$

(22)

$$X = |X_M - X_N|/r; Y = |Y_M - Y_N|/r; Z = |Z_M - Z_N|/r; r = (X^2 + Y^2 + Z^2)^{1/2}; R = (X^2 + Y^2)^{1/2} \quad (23)$$

in eq 23.  $X_p, Y_p$ , and  $Z_p$  are the coordinates of atom P in the original coordinate system used to specify the positions of the atoms in the molecule.

The elements of the  $F$  matrix for the  $\alpha$ -spin electrons are given in eq 24-26. Equation 25 refers to off-

$$F_{kk} = W_k^{(M)} + \sum_{N \neq M} [k_x^2 V_{kN}^\sigma + (k_y^2 + k_z^2) V_{kN}^\tau] + q_k^\beta A_M^- + \sum_{m \neq k} (q_m^\alpha A_M^+ + q_m^\beta A_M^-) + \sum_i \sum_n^{(N)(N)} (p_{in}^\alpha + p_{in}^\beta) (kk, ln) \quad (24)$$

$$F_{km}^{(M)} = \sum_{N \neq M} [k_x m_x V_{kN}^\sigma + (k_y m_y + k_z m_z) V_{kN}^\tau] - p_{km}^\alpha A_M^+ + \sum_i \sum_n^{(N)(N)} (p_{in}^\alpha + p_{in}^\beta) (lm, ln) \quad (25)$$

$$F_{ki}^{(M,N)} = k_x l_x \beta_{ki}^\sigma + (k_y l_y + k_z l_z) \beta_{ki}^\tau - \sum_m \sum_n^{(M)(N)} p_{mn} (km, ln) \quad (26)$$

diagonal matrix elements between AO's  $\phi_k$  and  $\phi_m$  of the same atom M, while eq 26 refers to corresponding elements between AO's of two different atoms M and N. Here the electron repulsion integrals have been

left in their original form, over AO's set up in the original coordinate system; in order to evaluate them, the AO's  $\phi_k, \phi_l, \phi_m$ , and  $\phi_n$  for each pair of atoms M and N are transformed into the local coordinate system of Figure 2.

The calculations were carried out at the Computation Center of The University of Texas, using first a CDC 1604 digital computer, and later a CDC 6600. The program, while somewhat complex, followed a fairly conventional path. The integrals  $\beta_{km}$  and  $\gamma_{km}$ , and the quantities  $k_x$  etc. of eq 22, are first computed and stored. An initial  $F$  matrix is then set up, using assumed values for the  $q$ 's and  $p$ 's; in the case of hydrocarbons, we set the charge density ( $q$ ) equal to unity for each valence orbital, and each bond order ( $p$ ) equal to zero. The  $F$  matrix is then diagonalized, new  $q$ 's and  $p$ 's are computed, and the process is continued until the sum of the energies of the occupied orbitals converges to within a predetermined limit. The total electronic energy is then computed (eq 19) and the total bonding energy found from it by adding the core repulsion and subtracting the total energy of the isolated atoms. The following section indicates the procedure we have followed in estimating the various integrals and other quantities appearing in the treatment.

### Calculations of Integrals Etc.

The quantities appearing in this treatment are of five types: (a) valence-shell ionization potentials,  $W_k$ ; (b) one-center repulsion integrals,  $(kk, mm)$  and  $(km, km)$ ; (c) one-electron resonance integrals,  $\beta_{ki}$ ; (d) two-center repulsion integrals,  $\gamma_{ki}$ ; (e) the core repulsion and core-electron attraction. For reasons indicated above, we are prepared if necessary to treat any or all of these quantities as parameters, our sole purpose being to develop a reliable and general method for calculating heats of formation of molecules of all kinds (including transition states) with "chemical" accuracy. However, one must obviously try to minimize the number of arbitrary parameters in a treatment such as this; we have accordingly adopted the course of introducing parametric functions for the calculation of the various quantities, these functions containing the minimum number of parameters and being chosen on the basis of physical intuition. In this connection, empirical data for atoms can be regarded as free information, for we are concerned only with the heats of formation of molecules, not with their total binding energies. The true parameters in our treatment are those whose values must be fixed by reference to properties of specific molecules; the number of such "molecular" parameters must be kept as small as possible if the method is to be useful and convincing. The procedure we followed in the calculations reported here was as follows.

(a and b) **Valence-Shell Ionization Potentials and One-Center Repulsion Integrals.** These were estimated for carbon from spectroscopic data by the following<sup>4</sup> procedure. We represent the core of the carbon atom as the ion  $C^{4+}$ , consisting of the nucleus and two 1s electrons. The quantities  $W_s$  or  $W_p$  should then represent the energy of a 2s or 2p electron, respectively, moving in the field of this core, and one might therefore try to equate them to the appropriate fourth ionization potentials of carbon, *i.e.*

ever, the orbitals in  $\text{C}^{2+}$  are smaller than those in neutral carbon and their binding energies correspondingly greater; the quantities  $W_s$  and  $W_p$  were therefore chosen to give a best fit to the energies of various states of neutral and singly ionized carbon.

We assume that the repulsion between two valence electrons has the same value, regardless of the orbitals occupied by the electrons; for electrons of like spin, the repulsion is  $A^+$ , and for electrons of opposite spin,  $A^-$ . Thus the energy ( $E^1$  or  $E^3$ ) of a carbon atom in the singlet or triplet states  $(1s)^2(2s)^2$ , represented by single determinants with  $S_z = \pm \frac{1}{2}$ , respectively, are given in eq 28 and 29. The

singlet  $(1s)(\bar{1}s)(2s)(\bar{2}s)(2p)(\bar{2}p)$

$$E^1 = 2W_s + 2W_p + 2A^+ + 4A^- \quad (28)$$

triplet  $(1s)(\bar{1}s)(2s)(\bar{2}s)(2p_x)(2p_y)$

$$E^3 = 2W_s + 2W_p + 3A^+ + 3A^- \quad (29)$$

quantities  $A^+$  and  $A^-$  are related to the one-center repulsion integrals by eq 14 and 15.

In order to estimate  $A^+$  and  $A^-$  it is necessary to determine  $E^1$  and  $E^3$  from spectroscopic data. The single determinants in eq 28 and 29 do not of course correspond to true states of carbon. There are 15 possible configurations, corresponding to the possible partitions of two electrons between the three 2p AO's; these are listed in (30) and (31). In our approximation, all states with  $S_z = 0$

$$\begin{aligned} (\uparrow\downarrow) \rightarrow (\uparrow\downarrow) \rightarrow (\uparrow\downarrow) \rightarrow (\uparrow\downarrow) \rightarrow (\uparrow\downarrow) \\ (\uparrow\downarrow) \rightarrow (\uparrow\downarrow) \rightarrow (\uparrow\downarrow) \rightarrow (\uparrow\downarrow) \end{aligned} \quad (30)$$

states with  $S_z = \pm \frac{1}{2}$

$$(\uparrow\uparrow) \rightarrow (\uparrow\uparrow) \rightarrow (\uparrow\uparrow) \rightarrow (\uparrow\downarrow) \rightarrow (\uparrow\downarrow) \rightarrow (\uparrow\downarrow) \quad (31)$$

"singlet" configurations of (30) have the same energy while all those of (31) have energy  $E^3$ . In practice, 15 configurations correspond to the following 15 states of carbon.

one state

five substates ( $M = 2, 1, 0, -1, -2$ )

nine substates ( $M = 1, 0, -1; S = 1, 0, -1$ ) (32)

In order to obtain correct representations of these states, we should construct appropriate linear combinations of the configurations indicated in (30) and (31). The configurations of different multiplicity do not: the six triplet states of (31) lead only to six substates of  $^3P$  (those with  $S_z = \frac{1}{2}$  or  $-\frac{1}{2}$ ). Since these states have the same energy (that of the state  $^3P$ ), we equate this energy to  $A^+$ . The remaining states are the  $^1S$  and  $^1D$  states, and the three substates of  $^3P$  with  $S_z = 0$ . These are represented by a set of nine orthogonal linear combinations of the configurations of (30) and (31). Now it is easily shown that the total energy of such a set of linear combinations is the same as the sum of the individual energies of the original configurations; the total energy of the nine configura-

tions is of course  $9E^1$ , while that of the nine real states and substates is  $[(^1S) + 5(^1D) + 3(^3P)]$ , where  $(^1S)$ ,  $(^1D)$ , and  $(^3P)$  are the energies of the corresponding states. Hence

$$E^1 = \frac{1}{9}[(^1S) + 5(^1D) + 3(^3P)] \quad (33)$$

The configuration thus appears as a weighted mean or *barycenter*<sup>5</sup> of the appropriate states. The energies of barycenters can thus be calculated from spectroscopic data, and the results can then be used to determine the various one-center integrals  $A^+$ ,  $A^-$ ,  $W_s$ , and  $W_p$ .

This treatment of atoms may seem rather primitive, but it is fully justified by its practical success.<sup>5</sup> The number of appropriate barycenters for a given atom is usually greater than the number of parameters; the energies of all the barycenters are given well by this approach for a wide variety of different atoms.

In calculating the binding energy of a molecule, we naturally compare its calculated total energy with a sum of the energies of ground-state barycenters of the component atoms, for, since we use a single Slater determinant to describe the molecule, it would be inconsistent not to use a similar description for its component atoms.

(c) The one-electron resonance integral  $\beta_{ki}$  can be interpreted physically as the energy of an electron occupying the overlap cloud between the AO's  $\phi_k$  and  $\phi_i$ , and moving in the field of the core and remaining electrons. We would therefore expect  $\beta_{ki}$  to be proportional (a) to the magnitude of the overlap cloud, i.e., to the overlap integral  $S_{ki}$ ; (b) to some mean of the binding energies of the AO's  $\phi_k$  and  $\phi_i$ ; (c) and to the distance between the overlap cloud and the nuclei of the atoms of which  $\phi_k$  and  $\phi_i$  are AO's. The last two conditions follow since the potential field in the overlap region arises mainly from the two atoms. We therefore adopted the following expression for  $\beta_{ki}$ .

$$\beta_{ki} = (\beta_{ki})_0 S_{ki} (I_k + I_i) [r_{ki}^2 + (\rho_k + \rho_i)]^{-1/2} \quad (34)$$

Here  $I_k$  and  $I_i$  are the valence-state ionization potentials of the AO's  $\phi_k$  and  $\phi_i$ , calculated for the appropriate barycenters by the method of ref 5;  $r_{ki}$  is the internuclear distance between the atoms of which  $\phi_k$ ,  $\phi_i$  are AO's;  $\rho_k$  and  $\rho_i$  are quantities appearing in the expressions for two-center repulsion integrals (see below);  $(\beta_{ki})_0$  is a parameter to be determined empirically, being the same for all valence orbitals of a given atom. The overlap integrals  $S_{ki}$  were calculated in the usual way using Slater-Zener orbitals ( $Z = 3.25$  for carbon). In order to reduce the number of parameters in the treatment, we assumed that  $\beta_0$  has a common value  $\beta_{xy}$  for orbitals of two atoms  $x$  and  $y$ , regardless of the type of orbitals (s or p) and mode of overlap ( $\sigma$  or  $\pi$ ), and that

$$\beta_{xy} = \sqrt{\beta_{xx}\beta_{yy}} \quad (35)$$

Equation 34 is more complicated than the corresponding expressions used by other authors; we have tried a number of such simpler expressions, but with less success. Thus omission of the terms  $I_k$  and  $I_i$  leads to results for unsaturated molecules such as ethylene in which the orbitals appear in the wrong order of energy; it is essential to use different values of  $\beta$  for s and p AO's. Again, omission of the term in  $r$  gave heats

of formation for acetylene that were much too low; it is apparently necessary to use for  $\beta$  an expression that increases more rapidly with decreasing bond length than does the corresponding overlap integral.

(d) The two-center integrals ( $\phi\phi, \psi\psi$ ) were estimated in two different ways, one for the CNDO calculations and one for the PNDDO approximation. The integral ( $\phi\phi, \psi\psi$ ) must in each case obey two boundary conditions. As the internuclear distance  $r$  tends to zero, the integral should approximate to a one-center repulsion integral, while, when  $r \rightarrow \infty$ , the integral should approximate to  $e^2/r$ .

In the CNDO calculations, we adopted expression 36, one which has been used successfully in previous work.<sup>3,6</sup> Here  $\rho_k$  and  $\rho_l$  are constants characteristic

$$\gamma_{kl} = e^2[r_{kl}^2 + (\rho_k + \rho_l)^2]^{-1/2} \quad (36)$$

of the two atoms, chosen to make  $\gamma_{kl}$  approach the corresponding one-center integral as  $r_{kl} \rightarrow 0$ ; i.e.

$$2\rho_k = e^2/A_k^- \quad 2\rho_l = e^2/A_l^- \quad (37)$$

In the second approach, different values were assumed for the integral  $\gamma_{kl}$ , depending on the nature of the orbitals involved and their mode of overlap. Two arguments guided us in choosing a suitable expression for the integrals. First, an analysis of the role of electron correlation, using a model<sup>6</sup> similar to that invoked in the SPO approach,<sup>6</sup> suggested that the integrals should fall into three distinct groups, i.e., (38)–(40).

$$\text{I. correlation large: } s\sigma:s\sigma; p\pi:p\pi; s\sigma:p\pi \quad (38)$$

$$\text{II. correlation medium: } s\sigma:p\sigma; p\sigma:p\pi \quad (39)$$

$$\text{III. correlation small: } p\sigma:p\sigma \quad (40)$$

Secondly, this subdivision of the integrals also appears in the values estimated theoretically, using Slater–Zener orbitals;<sup>7</sup> these are shown in Table I.

Table I. Values for Carbon–Carbon Two-Center Repulsion Integrals

Class	Type	Value of integral, ev	
		Calcd using Slater–Zener AO's	Calcd from (41)–(43)
1	$s\sigma:s\sigma$	9.28	
	$s\sigma:p\pi$	9.12	7.13
	$p\pi:p\pi$	8.98	
	$p\pi(x):p\pi(y)$	8.98	
2	$s\sigma:p\sigma$	9.61	7.81
	$p\pi:p\sigma$	9.41	
3	$p\sigma:p\sigma$	9.99	8.45

Our object was to duplicate this pattern, subject to the condition that the integral ( $ii, kk$ ) between orbitals of two identical atoms should converge to the corresponding one-center integral ( $ii, ii$ ) at zero internuclear separation. The expressions we adopted are given in eq 41–43, where in class II, the orbital  $\phi_k$  is the one of

Class I

$$(ii, kk) = e^2[r_{ik}^2 + (\rho_i + \rho_k)^2]^{-1/2} \quad (41)$$

Class II

$$(ii, kk) = e^2[r_{ik}^2 + (\rho_i + \rho_k T_{ik})^2]^{-1/2} \quad (42)$$

Class III

$$(ii, kk) = e^2[r_{ik}^2 + (\rho_i T_{ik} + \rho_k T_{ik})^2]^{-1/2} \quad (43)$$

the  $p\sigma$  type, and where

$$T_{ik} = e^{-r_{ik}/2(\rho_i + \rho_k)} \quad (44)$$

The values calculated in this way for carbon atoms at an internuclear distance of 1.55 Å are listed in the last column of Table I.

(e) **Core Repulsion.** Having calculated the total electronic energy ( $E_{el}$ ), we can then find the total energy of a molecule by adding to this the core repulsion. Our last problem is to decide how to calculate this.

In the  $\pi$  calculations, the repulsion between two cores M and N was set equal to the corresponding two-center repulsion integral; however, if we try to do this in the present case, we find that the molecule collapses to a point. The repulsion between point charges (i.e., the nuclear repulsion) is much greater at short distances than is the corresponding repulsion between clouds of charge representing occupied orbitals; this enhanced repulsion is one of the factors that keeps the atoms in a molecule at bond's length. In the  $\pi$  calculations, this difficulty did not arise since we assumed Morse functions for the  $\sigma$  components of bonds; here our calculations include all the valence electrons, so there is no escape.

Nor is it satisfactory to set the core repulsion equal to a point charge potential, i.e., to  $Z_M Z_N e^2/R$ , where  $Z_M$  and  $Z_N$  are the nuclear charges, for in this case the calculated binding energy is too small. The reason for this is implied in the literature. Consider for example  $H_2$ . The potential field in which the electrons move is greater than that in an isolated hydrogen atom; consequently, the orbitals of  $H_2$  are more compact than one would expect for a combination of ordinary 1s hydrogen AO's. Indeed, if we carry out an orbital treatment, regarding the nuclear charges ( $Z$ ) as variation parameters, we find the best agreement with experiment given by a value of  $Z$  considerably greater than unity. In our treatment, where the "atomic" parameters are fixed from spectroscopic data for isolated atoms, we assume in effect that the effective nuclear charge is the same for each atom in isolation as it is when the atom forms part of a molecule. In order to get realistic binding energies, either we must abandon this assumption or we must make some allowance for it by compensating changes in the other parameters. In this case the changes are best made in the nuclear repulsion, because this does not affect calculations of the electron distribution or orbital energies.

We therefore calculated the core repulsion from an appropriate parametric function. The function chosen must satisfy two boundary conditions. For large  $r_{ik}$ , it must approach the corresponding interelectronic repulsion between neutral atoms in order that the net potential due to a neutral atom should vanish at large distances, while for small  $r_{ik}$  it must have a value between this and that calculated for point charges. We

(6) See M. J. S. Dewar and N. L. Sabelli, *J. Phys. Chem.*, **66**, 2310 (1962).

(7) We are grateful to Dr. F. A. Matsen for these values.

ried a large number of possible one-parameter ons of this type; the most successful was that of

$$V = E_{MN} + [Z_M Z_N e^2 / r_{MN} - E_{MN}] e^{-\alpha_{MN} r_{MN}} \quad (45)$$

Here  $C_{MN}$  is the core repulsion between atoms  $M$  and  $N$ ;  $E_{MN}$  is the corresponding electronic repulsion between neutral atoms  $M$  and  $N$  (i.e.,  $(kk,mm)$  and over the valence orbitals);  $Z_M$  and  $Z_N$  are the core charges in units of  $e$  (i.e., the number of  $e$  electrons) of the two atoms;  $\alpha_{MN}$  is a parameter. In order to reduce the number of parameters in the treatment, we assumed (cf. eq 35) that the value of  $\alpha_{MN}$  for dissimilar atoms  $M$  and  $N$  is given in terms of parameters  $\alpha_{MM}$  and  $\alpha_{NN}$  for pairs of similar atoms

$$\alpha_{MN} = \sqrt{\alpha_{MM}\alpha_{NN}} \quad (46)$$

treatment contains very few "molecular" parameters, i.e., parameters whose value has to be determined from data for molecules rather than atoms. There are just two molecular parameters for each kind of atom  $X$ , i.e., the parameter  $\beta_{XX}$  that appears in the expression for one-electron resonance integrals involving orbitals of  $X$ , and the parameter  $\alpha_{XX}$  that appears in the expressions for corresponding core repulsion.

The attraction between an electron in an AO  $i$  of one atom  $M$  and the core of atom  $N$ , was set equal to the sum of repulsions between the electron and the core of  $N$  (cf. the corresponding approximation in the  $\pi$  treatment<sup>3</sup>).

### Application to Hydrocarbons

The method outlined above has been applied to a study of hydrocarbons. The general procedure was as follows: (a) the parameters  $\beta_{HH}$  and  $\alpha_{HH}$  were chosen to give the correct internuclear distance and bond energy for the  $H_2$  molecule; (b) assuming various values for  $\beta_{CC}$ ,  $\alpha_{CC}$  was varied to give the correct heat of formation for  $CH_4$ ; (c) heats of formation were then calculated for ethane, and propane, using the values of  $\alpha_{HH}$  from step a, and with the various pairs of values for  $\beta_{CC}$  and  $\alpha_{CC}$  from step b; (d) having thus determined optimum values for the parameters, calculations were carried out for a number of other saturated and unsaturated hydrocarbons.

In order to apply this treatment, it is necessary to specify the Cartesian coordinates of the atoms in a molecule; these must be calculated from the known (assumed) bond lengths and bond angles. In our calculations the positions of the atoms are specified by the bond lengths, bond angles, and dihedral angles of the molecule; we have written a program to calculate the coordinates of the atoms are calculated from these data. In the calculations reported below, we assumed tetrahedral geometry for  $sp^3$  carbon and planar geometry for  $sp^2$  carbon (bond angles,  $120^\circ$ ). Assumed bond lengths are shown in Table II.

The values for the parameters in the treatment are given in Table III, while Table IV compares calculated and observed heats of formation for the various compounds. Except when otherwise stated, saturated  $C_2$  compounds were assumed to have the conformation observed in ethane (i.e., one  $sp^3$  CH bond eclipsing the  $C=C$  bond).

Other calculated quantities will be found below (in discussion).

Y., 1962. <sup>f</sup> Calculated from the observed difference in energy between the *cis* and *trans* isomers; see Table V.

### Invariance to Rotation

As has been pointed out, the treatment used here is not strictly invariant to choice of coordinate axes, due to the neglect of repulsion integrals involving four  $p$  AO's of two different atoms. Four lines of argument suggested, however, that variations of this kind should be small. Firstly, integrals of this type represent quadrupole-quadrupole repulsions and are consequently much smaller than the charge-charge repulsions

corresponding to "normal" repulsion integrals; even in the case of adjacent carbon atoms, the integrals have values<sup>7</sup> of only about 0.1 ev. Secondly, the effect of changing the coordinate axes appears only as secondary changes in the values of these integrals, and the net effect in the sum of the integrals between a given pair of atoms should consequently be small. Thirdly, the integrals between a given pair of atoms do not all have the same sign; the resulting cancellations will further reduce their net contribution to the total energy and so likewise to its variation with choice of axes. And finally, the integrals in question, representing as they do higher multipole repulsions, decrease very rapidly with distance; integrals between nonadjacent atoms are essentially negligible.

Obviously, however, these arguments needed to be checked experimentally. We therefore repeated the calculations for a number of molecules in various orientations relative to the coordinate axes; in each case the eigenvalues, total energies, charge densities, and bond orders were identical with the accuracy with which they are printed (seven significant figures in the total energy, four in the other quantities). As a further check, we carried out calculations for carbon monoxide and hydrogen cyanide in various orientations; here again the results were quite unaffected by choice of coordinate axes, although these molecules contain heteroatoms and the neglected quadrupole-quadrupole integrals should be greatest for triple bonds since these are so short. It seems clear from these results that our procedure is for all practical purposes invariant to rotation of the coordinate axes, any variations being entirely negligible.

## Discussion

The agreement between the calculated and observed heats of formation in Table IV is rather remarkable, the differences in most cases being less than 4 kcal/mole (0.15 ev). The only serious discrepancies (~1 ev) occur in the case of allene and the acetylenes; these are probably due to our use of a nuclear potential which does not increase sufficiently rapidly at short distances. Thus our method correctly predicts the heat of formation (and so by implication the strain energy) of cyclopropane, in which the bonds are single; on the other hand, attempts to calculate bond lengths, by minimizing the total energy of a molecule with respect to them, have given values which are much too small.

Several other qualitative checks also seem satisfactory. Thus ethane is correctly predicted to be most stable in the staggered conformation, cyclohexane in the chair conformation, and 2-butene and 1,3-butadiene in *trans* configurations; previous SCF MO calculations for 1,3-butadiene had incorrectly predicted the *cis* form to be more stable.<sup>8</sup>

Admittedly the differences in energy are not predicted exactly; this is clear from the data listed in Table V. In one case our procedure even leads to a qualitatively incorrect prediction, *i.e.*, that normal paraffins should be more stable than their branched isomers, while the predicted barrier to rotation in ethane is too small. Nevertheless, the over-all picture is very encouraging, given that the work described here represents only a preliminary approach to the problem and given

that the errors in the calculated heats of formation are less by two orders of magnitude than those derived from other recent SCF MO calculations.<sup>4,9</sup>

<sup>a</sup> J. G. Aston, *Discussions Faraday Soc.*, **10**, 73 (1951).

The objective of these calculations was admittedly different from ours. Both Pople and Segal<sup>4</sup> and Lipscomb, *et al.*,<sup>9</sup> were trying to devise some simple semiempirical MO procedure that would reproduce the results to be expected from an *a priori* Roothaan-type approach. The parameters were therefore chosen in such a way as to make the results of the two calculations agree for small molecules where *a priori* calculations have, or could, be made. This procedure of course ensured that the semiempirical treatments would give poor estimates of heats of formation, seeing that heats of formation calculated by the Hartree-Fock method are known to be very inaccurate.

Another check on our work is provided by the photoionization potentials measured for various hydrocarbons by Al-Joboury and Turner.<sup>10</sup> The ionization potentials of a molecule should, according to Koopman's theorem, be approximately equal to the calculated orbital energies; Table VI shows that this parallel exists in a remarkable way for a variety of hydrocarbons and for all measured ionization potentials up to about 19 ev. The photoionization spectra show numerous peaks in this region, due to the possibility of producing ions in vibrationally excited states; our calculations suggest that in several cases Turner, *et al.*,<sup>10</sup> may have mistaken multiple peaks as being due to different vibrational states of a single ion, rather than to two or more different ions of similar energy. Similar difficulties arise in attempts to correlate observed electronic spectra of molecules with calculated excitation energies.

The last column of Table VI shows orbital energies calculated by Palke and Lipscomb<sup>9b</sup> by an *a priori* SCF LCAO MO method, using the POLYATOM program. It will be seen that their orbital energies run parallel to ours but are in general greater; the correlation with measured photoionization potentials is clearly poor. Another comparison of this kind is provided by the population analyses shown in Table VII; here again our values run parallel to those given by the *a priori* procedure and also to those reported by Pople and Segal.

Our method predicts small dipole moments for several of the compounds studied; values are listed in Table VIII. The available experimental evidence (last column

approach has exciting possibilities. It seems very likely that it may be improved to a point where heats of formation, etc., of molecules of all kinds may be predicted with an accuracy comparable with that already achieved for conjugated hydrocarbons, using the Hückel approximation. If so, the impact on chemistry would be considerable, for not only would one be able to calculate heats of formation and reaction with "chemical" accuracy, but it would also be possible to predict reaction mechanisms and rates of reaction.

Our results represent a considerable improvement over those of previously reported investigations. The main factors responsible for this seem to be the following: (a) our treatment of the internuclear repulsion as a parameter to allow for the effects of orbital contraction (if the repulsion is treated as one between point charges, the calculated heats of formation must inevitably be too small); (b) our use of different integrals for s and p AO's of a given center, together with a sufficient inclusion of integrals involving one-center differential overlap to make the calculations effectively invariant to choice of coordinate axes; (c) our use of thermochemical data to fix the parameters in our treatment, rather than the results of *a priori* calculations.

There are several obvious ways in which this general approach could be modified and extended, in particular the use of Hartree-Fock AO's in the calculation of over-

(11) For this reason we have not reported the results (e.g., eigenvalues, eigenvectors, bond orders, etc.) in detail; we will be happy to communicate them to anyone interested.

lap integrals and the use of separate parameters for different types of bonds in place of the approximations of eq 35 and 46. We are studying these and other analogous possibilities, and we are also extending our

treatment to include all integrals involving one-center differential overlap (NDDO approximation<sup>5</sup>) in case this should prove necessary in treating molecules containing heteroatoms.

## Reversible Photoisomerization of 1,2-Bis(9-anthryl)ethane<sup>1</sup>

Robert Livingston<sup>2</sup> and Kei Sin Wei

Contribution from the Division of Physical Chemistry, University of Minnesota, Minneapolis, Minnesota. Received January 21, 1967

**Abstract:** The hydrocarbon 1,2-bis(9-anthryl)ethane (I) is photoisomerized efficiently and reversibly. The isomeric product (II) does not absorb appreciably at wavelengths longer than 260 m $\mu$ . The quantum yields of the forward and back reactions (0.19 and 0.42, respectively) are independent of the concentration of the reactant. Compound I is strongly fluorescent with maxima at 408, 436, and 460 m $\mu$ , and a fluorescent quantum yield of about 0.37. Flash illumination of its deoxygenated solutions produces an absorption transient, similar to but not identical with the lowest triplet of anthracene. No attempt was made to observe the fluorescence or triplet formation of the isomer (II).

The hydrocarbon 1,2-bis(9-anthryl)ethane (I) is efficiently and reversibly photoisomerized.<sup>3</sup> The detailed structure of the photoproduct (II) has not been

established definitely. However, as was clearly stated by Roitt and Waters,<sup>3a</sup> its ultraviolet absorption spectrum is in general similar to that of dianthracene,<sup>4</sup> demonstrating that in II the conjugation of the anthracene rings is interrupted. It was postulated<sup>3a</sup> that II is a dimer of I, but molecular weight determinations (with a Mechrolab osmometer<sup>3b</sup>) prove that it is an isomer rather than a dimer of I. Our present finding, that the quantum yields of the photochemical reactions are independent of the concentrations of the reactants, confirms this conclusion unambiguously. Physical evidence (nmr, infrared, and mass spectrographic measurements<sup>5</sup>) is consistent with formula II.

Compound II is stable at room temperature (in the absence of ultraviolet radiation) but isomerizes at its melting point, re-forming I.

Since the product II does not absorb appreciably at wavelengths longer than 260 m $\mu$ , the quantum yield of the forward reaction was measured directly, using light

of 365 m $\mu$ . The quantum yield of the reverse reaction was estimated from the extinction coefficients, the quantum yield of the forward reaction, and the composition of a steady-state mixture, prepared by prolonged exposure to 254 m $\mu$ .

### Experimental Section

**Methods and Materials.** Materials. The 1,2-bis(9-anthryl)ethane was furnished by Dr. S. Fenton (University of Minnesota). It was recrystallized from *n*-hexane before use. The cyclohexane was Fisher Spectro Grade and was used without further purification.

**Determination of Quantum Yields.** The intensity of the absorbed light was determined by the use of a ferrioxalate actinometer, following the procedure outlined by Parker.<sup>6</sup> The absorption of the incident light was practically complete, except for those experiments made with the most dilute solutions; for these, the percent absorption was calculated from the extinction coefficients. Light of the required wavelengths was isolated from the radiation of a Hanovia S-100 mercury arc, using combinations of glass, solution, and Cl<sub>2</sub> gas filters.<sup>7</sup>

**Optical Measurements.** The absorption spectra were measured with a Cary 15 spectrophotometer. The fluorescence spectrum was measured by T. Bednar of this department, using a deaerated,  $5 \times 10^{-5}$  M solution of I in cyclohexane and exciting light of 370 m $\mu$ . The fluorescence was observed at right angles to the exciting beam. The spectral resolution of the fluorimeter was estimated to be 10 Å. The spectrum was corrected for variation of the sensitivity of the apparatus with wavelength but not for reabsorption, which probably seriously distorted the curve at wavelengths shorter than 400 m $\mu$ . Qualitatively similar results were obtained by K. S. W., using a manually operated spectrofluorimeter.<sup>7</sup>

### Results

The absorption and fluorescence spectra of I are shown on Figure 1; the absorption spectrum of its isomer (II) is shown on Figure 2. The quantum yield of fluorescence of I was estimated to be 0.37, by comparing its total emission to that from anthracene, for which the fluorescence yield (measured under similar conditions) is 0.31.<sup>8</sup>

Carefully deoxygenated,  $10^{-5}$  M solutions of I exhibited large transient changes in absorption, when

Figure 1. Absorption and emission spectra of 1,2-bis(9-anthryl)ethane in cyclohexane. The scale for absorption between 220 and 70  $m\mu$  is reduced by a factor of 10. The emission spectrum is plotted as intensity in arbitrary units. It is corrected for variation of instrumental sensitivity with wavelength but not for reabsorption, which seriously distorts the curve at wavelengths shorter than 400  $m\mu$ . Absorption is indicated by a solid line, emission by a dash line.

subjected to flash illumination, under conditions which have been described elsewhere.<sup>9</sup> The maximum of this transient occurred at 445  $m\mu$ , about 15  $m\mu$  longer than the wavelength of the maximum of the anthracene triplet. The half-life of the transient was approximately  $1.5 \times 10^{-8}$  sec. An anthracene solution, prepared in a similar way, showed a half-life of  $3.0 \times 10^{-8}$  sec. These half-lives are minimum values and are probably much shorter than the values which correspond to the spontaneous unimolecular decay of the triplet state.<sup>10</sup> The observed difference between the values of the half-lives for anthracene and I is probably due to differences in the residual oxygen concentration in the two solutions.

Quantum yields of isomerization of I, in cyclohexane, are summarized in Table I. Generally similar results

were obtained using benzene as the solvent. Over a 20-fold range the yield is independent of the concentration of the reactant. The apparent dependence on temperature is of doubtful significance but, if real, corresponds to an energy of activation of about 400 cal/mole. Oxygen has a small but definite inhibiting effect. This effect cannot be explained as due to peroxide formation, since its occurrence would increase the apparent quantum yield of dimerization.

Quantum yields for the back reaction, which are listed in Table II, were calculated from the steady-state compositions; they depend on the measured values of the extinction coefficients, the quantum yield of the forward reaction, and the assumption that this yield is the same for 365 and 254  $m\mu$ . Light of 254  $m\mu$  was used to produce the steady state. Effects of the reactant concentration, oxygen, and temperature are similar to those observed for the forward reaction.

## Discussion

The observation that the quantum yield of isomerization is not affected by a 20-fold change in the concentration of the reactant indicates that the reaction is a

unimolecular rearrangement of the electronically excited molecule. This unimolecular reaction must compete with the spontaneous (radiative and nonradiative) decay of the excited state and with its quenching by oxygen. Measurements, made by M. Walker of this department with a phase shift apparatus<sup>11</sup> using a deaerated  $5 \times 10^{-5} M$  solution of I in cyclohexane, indicate a mean lifetime of fluorescence of  $2.5 \times 10^{-9}$  sec. The rate constants for the spontaneous decay of the triplet and for the oxygen quenching of the first excited singlet and the lowest triplet have not been determined for I. It is plausible that they are in general similar to the corresponding values for anthracene, which are as follows: first-order decay of the triplet,  $30 \text{ sec}^{-1}$ ; <sup>12</sup> second-order (oxygen) quenching of the excited singlet,  $2.3 \times 10^{10} \text{ l./mole sec}$ ; second-order quenching of the triplet, <sup>12</sup>  $2.3 \times 10^9 \text{ l./mole sec}$ .

(12) R. Livingston, "Flash Photolytic Studies" in "Actions Chimiques et Biologiques des Radiations," Masson et Cie, Paris, 1966.

Values of these orders of magnitude preclude the possibility that the active intermediate for isomerization is exclusively the triplet state. The postulate that the observed reaction is the result of a spontaneous rearrangement of the fluorescent state is consistent with the observed values for air- and oxygen-saturated solutions. However, the relatively high value obtained for deoxygenated solutions is incompatible with this mechanism. This value, if correct, suggests that both the excited singlet and the triplet states can isomerize, but that the triplet state contributes significantly to the reaction only in deoxygenated solutions.

**Acknowledgment.** We wish to express our gratitude to Dr. S. Fenton (Minnesota) for suggesting this problem and providing the sample of 1,2-bis(9-anthryl)ethane, and to Dr. R. Lumry (Minnesota) and his colleagues, Dr. T. Bednar and Dr. M. Walker, for determining the fluorescence spectrum and mean lifetime.

## Electron Spin Resonance Studies on Ion Pairing in Semiquinone-Alkali Metal Systems

M. P. Khakhar, B. S. Prabhananda, and M. R. Das

*Contribution from the Tata Institute of Fundamental Research, Bombay 5, India.  
Received December 27, 1966*

**Abstract:** ESR spectra from semiquinone anion radicals produced by alkali metal reduction of parent quinones in ether solvents have been investigated. The results reveal large changes in the spin density distribution in the semiquinone rings as a consequence of association of the anion with alkali metal cations. Ion pairs with different amounts of solvation have been detected, and the results have been interpreted in terms of an ion-pair equilibrium model. Alternating line-width effects have also been observed in the semiquinone-alkali metal system. This arises from the time-dependent modulations of the isotropic ring proton splitting constants resulting from an equilibrium between "solvated" and "intimate" ion pairs in which the metal cation does not drift away from the radical anion.

There has been considerable interest in the experimental and theoretical investigations of the electron spin resonance (esr) of semiquinones in the recent past. The semiquinones form a convenient system for such investigations for various reasons, like ease of producing radicals using different methods and the simplicity of their esr spectra. *p*-Benzosemiquinone (PBSQ), which forms the simplest member of the semiquinone type of radicals, has been investigated extensively, and accurate data are available for hyperfine splittings from protons<sup>1-12</sup> and carbon-13<sup>13-20</sup> and oxygen-17<sup>21,22</sup> nuclei.

ful technique in producing aromatic radicals has the reduction of the parent material in a polyether alkali metals; the method has been described previously.<sup>24-27</sup> A variety of interesting results have been obtained on the alkali metal-aromatic radical ion obtained in this manner. The interest centered around the structure of ion pairs,<sup>28-30</sup> the differences of ionic equilibria existing in the radical-metal system,<sup>28,30,39-43</sup> and the effect of intramolecular and intermolecular interactions on the esr.<sup>30,34,39-42</sup> The observation of an alternation broadening in the esr spectra resulting from an molecular exchange of a cation first observed by Eyring and Mackor<sup>41,42</sup> and supported by later studies<sup>23,34</sup> has been of particular interest.

The present work was undertaken with a view to investigate the ion-pairing phenomenon in the semiquinone-alkali metal system in detail using the alkali reduction technique in ether solvents. From experimental observations<sup>10-12,18-20,22</sup> one expects large perturbations in the unpaired electron in the semiquinone ring systems as a consequence of ion pairing. The expectations have been substantiated by esr results. The results obtained on semiquinones with different alkali metals using 1,2-dioxethane (DME) and tetrahydrofuran (THF) are presented together with the temperature dependence of the splittings as reported in section III. These results and the mechanism of the alternation in line splitting that we have observed in the present system

are discussed on the basis of an ion-pair equilibrium model in section V.

## II. Experimental Section

*p*-Benzoquinone was prepared from hydroquinone (May & Baker Ltd.) according to the method of Gilman and Blatt<sup>44</sup> and was purified by sublimation (mp 116°). Duroquinone was synthesized starting from durene (Fluka, Switzerland) using known methods.<sup>45</sup> The product was crystallized from ethanol and purified by vacuum sublimation (mp 111°). 2,6-Dichloroquinone was obtained from Eastman Organic Chemicals and was purified by vacuum sublimation before use. DME and THF were obtained commercially. The solvents were purified according to methods described previously.<sup>27,46</sup>

The semiquinone radicals were made *in vacuo* by reducing the corresponding quinones with alkali metals using known techniques.<sup>24-27</sup>

The X-band esr spectrometer used has been described previously.<sup>12</sup> The temperature studies were made using a Varian V-4540 temperature-control unit. The details of field calibration have been described elsewhere.<sup>47</sup>

## III. Experimental Results

*p*-Benzoquinone Ion (PBSQ). The results obtained on PBSQ with sodium and potassium as gegenions using DME as solvent are given in Table I.

The PBSQ-K sample in DME was bluish green in color and was stable for 36-48 hr. Afterwards the radicals gradually decayed. At room temperature the esr spectrum from this sample was qualitatively similar to those observed for PBSQ by air oxidation of hydroquinone or by the electrolytic reduction of *p*-benzoquinone, and the hyperfine splitting arises from the interaction of the unpaired electron with four equivalent protons. However, on cooling the sample, the spectrum gradually changed its shape. At -20°, lines with total  $z$  component of the proton nuclear spin angular momentum  $M_H = \pm 1$  were broadened and were comparable in intensity to lines with  $M_H = \pm 2$ . At -60°, a nine-line esr spectrum was observed, and it has been reported in a preliminary communication.<sup>12</sup> This spectrum has been attributed to a radical species which has two sets of two equivalent protons.

In Table I, the radical species in which the four ring protons are equivalent is referred to as the "A" species, and the one in which they form two sets of equivalent groups is referred to as the "B" species. The same terminology will be used in discussing the results from durosemiquinone (2,3,5,6-tetramethyl-*p*-benzoquinone) also. Radical species in which all the four

methyl groups are equivalent will be designated as the "A" species, and the one in which they fall into two groups of equivalent protons will be referred to as the "B" species.

The PBSQ-Na sample in DME was also bluish green in color, but it was less stable, and it was necessary to complete the esr measurements within 10–12 hr after the sample was prepared. The room-temperature spectrum was a superposition of two spectra, one from the A species with one proton splitting constant and another from the B species with two proton splitting constants. The spectrum from the B species shows additional structure due to  $^{23}\text{Na}$  ( $I = 3/2$ ) hyperfine interaction (see Table I). However, the relative concentration of the two species could not be correctly determined as a result of the highly overlapped nature of the experimental spectrum. At  $-20^\circ$  the lines were considerably broadened, and it was not possible to obtain accurate data from the spectrum. The sample showed the same behavior even on further cooling.

Attempts to record esr spectra from PBSQ-Li in DME and PBSQ-M ( $M = \text{Li, Na, K}$ ) in THF were not successful as the radicals were found to be unstable.

**Durosemiquinone Ion (DSQ).** Unlike PBSQ, samples of DSQ with lithium, sodium, and potassium as counterions were quite stable in both DME and THF. The results obtained from these samples are reported in Tables II and III.

**DSQ-K Samples.** When the radical was prepared with potassium metal in DME, the sample exhibited esr spectra with equally spaced components at room temperature and at  $60^\circ$ . These could readily be in-

Figure 2. First derivatives of the esr spectra from durosemiquinone ion in DME with sodium as counterion.

terpreted as arising from 12 equivalent methyl protons (A species). However, the room-temperature spectrum showed dormant alternating line-width effects. At  $-20^\circ$  the alternating line-width effect was considerably enhanced (Figure 1), and as the temperature was further lowered lines arising from the B species started appearing. At  $-80^\circ$ , the spectrum could be interpreted in terms of two groups of equivalent protons, each consisting of six protons and arising from pure B species. A sample of DSQ-K in THF solution behaved essentially in the same manner. However, at room temperature there was larger alternation in the width of the lines in the esr spectrum from this sample as compared to the spectrum from DSQ-K in DME. No potassium splittings were observed in either case.

**DSQ-Na Samples.** The spectra from this sample in DME at different temperatures are shown in Figure 2. Except at  $-80^\circ$ , at all other temperatures reported in Table II, the individual figures arise from both A and B species of DSQ. Both species show hyperfine splittings arising from  $^{23}\text{Na}$  hyperfine interaction (see assignments of splitting constants below). A different extent of alternation in the line broadening at different temperatures is also evident in Figure 2.

In interpreting the spectra from DSQ-Na samples, the equally spaced four-line pattern arising from the A species could be easily picked out. The problem was then reduced to assigning the rest of the lines to B species. In order to do this, spectra were reconstructed

<sup>a</sup> See text for definition of "A" and "B" species. <sup>b</sup> No metal splitting observed in the spectra. <sup>c</sup> No A species observed for the sample.

and compared with the experimental one. In doing so, it was assumed that the sum of the two proton splitting constants,  $a_1^H$  and  $a_2^H$ , for the B species is twice the proton splitting constant,  $a^H$ , for the A species. This is justifiable as it holds true for all other spectra from B species. Consequently, the individual values of  $a_1^H$  and  $a_2^H$  were varied keeping their sum constant. Different values of  $a^{Na}$  were then used for computing each spectrum.

Taking the -60° case as a typical representative of the group, stick plots were constructed and were compared with the experimental spectrum. After successfully interpreting the -60° spectrum, it was possible to pick out typical patterns arising from the B species in the overlapped spectra at other temperatures, and an intelligent guess regarding the splitting constants from the B species could be made. Stick diagrams were then reconstructed which explained all the observed lines in the experimental spectrum.

The splitting constants for the B species at 80° and at room temperature could not be calculated because of the broadening of the lines in the region where lines from the B species were expected. Consequently, no assignments of proton splitting constants for the B species could be made at these temperatures. The values of the splitting constants in DME are reported in Table II.

The DSQ-Na sample in THF behaved in a slightly different fashion. At all the temperatures at which

investigations were carried out, only the B-type of spectra were observed. They exhibited  $^{23}\text{Na}$  hyperfine splittings. No alternation in the widths of hyperfine components were observed in this case. The splitting constants are reported in Table III.

**DSQ-Li Samples.** Samples of DSQ-Li in both DME and THF behaved essentially in the same manner. The spectra at different temperatures could be explained in terms of B species spectra with two splitting constants, each arising from six equivalent protons. There was no observable Li metal splitting unlike the experiments in *t*-pentyl alcohol,<sup>23</sup> and no alternating line-width effects were present. A typical spectrum from the DSQ-Li sample is given in Figure 3. The splitting constants are reported in Tables II and III.

In all instances where the presence of a B species with two splitting constants could be detected, the larger splitting constant,  $a_2^H$ , increases with temperature and the smaller one,  $a_1^H$ , decreases with temperature. The variation depends on the solvent and the counterion used, and this will be discussed later. The proton splitting constant,  $a^H$ , for the A species does not show any measurable temperature variation, although the  $^{23}\text{Na}$  splittings in both the A and B species increase with temperature (Tables II and III).

**2,6-Dichlorosemiquinone Ion (2,6-DCSQ).** Solutions of 2,6-DCSQ in DME and THF were green in color. The radicals were unstable and they decayed completely in 1-1.5 hr. The expected<sup>6</sup> three-line spec-

Figure 3. First derivative of the ESR spectrum from durosemi-quinone ion in DME with lithium as counterion.

Figure 4. *p*-Benzosemiquinone anion.

trum, with approximate intensity distribution 1:2:1, arising from two equivalent protons was observed from all the samples from which signals could be recorded. However, except for 2,6-DCSQ-K in DME, all the other samples in DME as well as in THF gave spurious ESR signals which could not be attributed to any simple radical species arising from 2,6-dichloroquinone. The correct lines from 2,6-DCSQ could be easily identified from intensity considerations and spacings of the hyperfine components. There was no change in the number of lines with temperature, and no alkali metal splittings were present either. Consequently, little information could be obtained by making extensive temperature studies. The results obtained at room temperature and at  $-75^\circ$  are given in Table IV. For all the samples, careful measurements have shown a difference in the proton hyperfine splitting with temperature, contrary to a preliminary report.<sup>12</sup> The proton splitting constant increases with temperature for all samples, and at the same temperature the DME samples show a larger splitting as compared to THF samples.

Table IV. Proton Splitting Constants (gauss) for 2,6-Dichlorosemiquinone Anion

-75	2.139	2.943	...	3.124

<sup>a</sup> No metal splitting observed in the spectra.

#### IV. Assignments of Splitting Constants

**1. Assignments of Proton Splittings in B Species.** There is no ambiguity in the assignment of proton splittings for the A species radicals. Once the proton splittings are assigned, it is not difficult to make assignments for the alkali metal splittings also. However, the spectra from the B species result from two equivalent groups of protons as a consequence of ion-pair association. The positions 2, 3, 5, and 6 (see Figure 4) in a *p*-benzosemiquinone ring can be divided into two equivalent groups in any one of three ways, (a) 2,5 and 3,6; (b) 2,3 and 5,6; or (c) 2,6 and 3,5. However, it is possible to make a satisfactory choice in the following manner. Previous experimental investigations<sup>10-12,18-20</sup> on the semiquinone radicals indicate that most interactions with the surroundings take place through the oxygen atoms in the semiquinone ring. Consequently, the most probable position of the alkali metal counterion also is near one of the oxygens which has maximum charge density.<sup>20</sup> If this assumption is

made, the best possible division will be to have the 2 and 6 positions in one group and the 3 and 5 positions in the other. There is experimental evidence to support this view. For 2,6-DCSQ one expects association with the counterion at least to the same extent as in the case of either PBSQ or DSQ owing to the presence of two electronegative chlorine atoms in the ring. When there is strong association, one expects a four-line spectrum from 2,6-DCSQ if either of the groupings a or b were correct. On the other hand, the spectra from 2,6-DCSQ showed only three hyperfine components at all conditions, irrespective of the difference in the temperature of the experiment, the metal cations, and the solvents used, although the magnitude of the splittings changed considerably under different experimental conditions.

**2. Position of Counterion and Magnitude of Ring Proton Splittings.** From the experimental data alone it is difficult to assign the splittings,  $a_1^H$  and  $a_2^H$ , in PBSQ and DSQ to specific positions in the molecule. The problem arises, in the case of the B species, whether the larger splitting constant,  $a_2^H$ , should be assigned to the group of protons that are nearer to the oxygen atom complexed with the alkali metal or to those farther away from it. A satisfactory assignment is, however, possible by comparing the temperature dependence of the splittings in PBSQ and DSQ with that of 2,6-DCSQ (see section V2).

It is reasonable to assume that in the "intimate" species of 2,6-DCSQ the metal cation is near the oxygen atom having two chlorine atoms as neighbors because of the higher electronegativity of the chlorines as compared to protons.<sup>48</sup> It is experimentally observed that the proton splitting constant for 2,6-DCSQ increases with temperature. It may therefore be assumed that the splitting from protons away from the metal cation increases with temperature. On this basis the larger splitting constant,  $a_2^H$ , in *p*-benzo- and durosemiquinones, which shows a positive temperature coefficient, can be assigned to protons farther away from the metal cation and the smaller splitting constant, which decreases with temperature, to protons nearer to the metal cation. It may also be noticed that the effect of association at an oxygen site in the semiquinone is to increase the electronegativity of the oxygen atom, which results in the use of a larger numerical value for the Coulomb integral parameter for the complexed oxygen.<sup>20</sup>

(48) It may be noticed that Lücken<sup>11</sup> has reported the existence of two types of "intimate" ion pairs for 2,6-DCSQ in anhydrous *t*-butyl alcohol, the major fraction having the alkali metal complexed to the oxygen atom flanked by the chlorine atoms and a small fraction with the alkali metal complexed to the oxygen flanked by protons. It has also been observed that simple MO theory predicts larger association at the oxygen flanked by chlorine atoms.

Lücken<sup>11</sup> has shown that simple MO theory predicts an increase in the splitting constant of one pair of protons with a simultaneous decrease in the splitting constant of the other pair as a result of complex formation involving one of the oxygen atoms. Lücken<sup>11</sup> has noticed further that the pair *ortho* to the complexed oxygen atom has a lower coupling constant.

## V. Discussion

**1. The Ion-Pair Equilibrium Model.** The additional hyperfine structure arising from <sup>23</sup>Na nuclei in the esr spectra from PBSQ-Na and DSQ-Na in DME and THF suggests the formation of ion pairs in these systems. Even in the absence of alkali metal hyperfine splitting, the observation of esr spectra from the B species, when potassium and lithium are used as counterions, supports ion-pair formation. Further, experimental evidence from both PBSQ and DSQ reveals the presence of more than one type of ion pair which are interconvertible. The best evidence for the simultaneous existence of two types of ion pairs is obtained from DSQ-Na in DME. ESR lines from both A and B types of radical with different <sup>23</sup>Na splittings have been observed in this case. Presumably, the ion pairs differ from each other in their different extents of solvation. The formation of ion pairs with different amounts of solvation has been observed by other workers also.<sup>39,49-54</sup> Hirota<sup>39</sup> has observed different distinct solvated species in the naphthalene negative ion, where the radical species have different <sup>23</sup>Na splittings, although the magnitude of the proton splittings remains unchanged. In the present instance, as a consequence of stronger association between the alkali metal and the radical, we do observe changes in both proton splittings and alkali metal splittings in species that are solvated to different extents. In fact, the results reported in section IV can be satisfactorily explained on the basis of an ion-pair equilibrium model in which an "intimate" or "contact" ion pair is in equilibrium with a "loose" or "solvated" ion pair. The different possible equilibria for a species with a given nuclear spin state are indicated below (Figure 5). Species of the type M<sup>+</sup>||R<sup>-</sup> represent the solvated ion pair, and the ones of the type M<sup>+</sup>R<sup>-</sup> represent the intimate pairs.

In the intimate pairs, the alkali metal cation is close to one of the oxygens, and this perturbs the unpaired electron distribution in the semiquinone ring. Two sets of equivalent ring positions are formed resulting in the B type of radical exhibiting two proton splitting constants,  $a_1^H$  and  $a_2^H$ . In the solvated pair, which corresponds to the A type of radicals, the equivalence of the four ring proton positions is retained as the alkali metal is farther separated from the oxygen atom by the solvent layer.

If the metal ion does not leave the vicinity of the radical anion, equilibria 1 and 2 (Figure 5) can be considered to be intramolecular processes insofar as the preservation of the spin state of the metal nucleus during the conversion is concerned. Equilibria 3 and 4 are intermolecular processes in which the metal cation

Figure 5. Different possible ion-pair equilibria for *p*-benzosemiquinone ion with a given nuclear spin state.

from the oxygen at one end of the molecule gets detached from the anion, and another cation from the surroundings gets associated with the anion at the other end. However, owing to the presence of sharp alkali metal lines even in spectra exhibiting alternating line widths, it may be argued<sup>42</sup> that intermolecular processes are absent in the system. The preservation of the spin state of the alkali nucleus during the exchange process, which is fulfilled by the intramolecular processes 1 and 2, can then explain all the observed effects satisfactorily. Thus equilibria 1 and 2 which can be simply represented by

need only be considered. This assumes that each alkali metal, to begin with, is associated with a radical ion in the form of either a solvated or an intimate ion pair.

**2. Temperature Dependence of Splitting Constants and Structure of Ion Pairs.** de Boer<sup>55</sup> has noticed that, although two splitting constants are observed for the aliphatic protons (which are equivalent in the absence of association) in pyracene anion, their values remain unchanged with any variation in temperature. However, in the durosemiquinone-alkali metal system (Tables II and III), it has been observed that the smaller splitting constant,  $a_1^H$ , decreases with temperature and the larger splitting,  $a_2^H$ , increases with temperature. Table V gives the difference in the two splitting constants ( $a_2^H - a_1^H$ ) at various temperatures for durosemi-

quinone with different counterions in DME and THF. Table V shows several interesting features. The values of  $(a_2^H - a_1^H)$  increase as the temperature of a given sample is increased. The increase is more for a THF solution as compared to a DME sample at a given temperature, and for different alkali metals the value increases in the order  $\text{Li} > \text{Na} > \text{K}$ . From Tables II and III it is also clear that just like  $(a_2^H - a_1^H)$ , the sodium splitting,  $a^{\text{Na}}$ , also has a positive temperature coefficient.

Table V. Temperature Variation of  $(a_2^H - a_1^H)$  in B Species of Durosemiquinone Anion (gauss)

Temp, °C	Li		Na		K	
	DME	THF	DME	THF	DME	THF
60	2.351	...	...	...	...	...
25	2.118	2.224	...	1.683	...	...
-20	1.923	2.095	1.285	1.455	...	1.221
-40	...	2.060	...	1.415	...	1.173
-50	1.808	...	...	...	0.998	...
-60	...	1.981	1.282	...	...	1.108
-70	1.763	...	...	...	0.973	...
-80	...	...	...	...	0.968	1.124

These results are understandable if we assume the position of the alkali metal ion to be near one of the oxygen atoms in the semiquinone and close to the plane containing the atoms in the ring, which forms a nodal plane for the  $\pi$  molecular orbital containing the unpaired electron.<sup>37,42,55</sup> The alkali metal may further be assumed to undergo oscillations<sup>55</sup> in a potential well at this position. In such a model, the effect of increasing the temperature or of decreasing the mass of the counterion will be to enhance the amplitude of the oscillations. Enhanced oscillation should result in the counterions spending more time away from the nodal plane, causing larger perturbation in the  $\pi$  molecular orbital. As the difference in ring proton splittings is caused by the perturbation induced by the counterion situated near one of the oxygen atoms, it is reasonable to expect the value of  $(a_2^H - a_1^H)$  to increase with a larger amount of perturbation (see also section IV2).

A change in  $(a_2^H - a_1^H)$  can also arise from a change in equilibrium constants.<sup>56</sup> However, in cases where only the B-type radical is present at all the temperatures, as in the case of Li-DSQ in DME and THF and Na-DSQ in THF, the variation in  $(a_2^H - a_1^H)$  may be arising from the oscillational mechanism.

**3. Alternating Line Widths in Semiquinone Anions.** Several instances of alternation in line broadening in the esr spectra of free radicals have been reported in the literature,<sup>23,24,37,42,57-61</sup> and this phenomenon is

understood in a satisfactory fashion. However, it has been shown by de Boer and Mackor<sup>41,42</sup> that a novel mechanism, *viz.*, an intramolecular migration of the alkali metal cation between two equivalent sites in a radical, can give rise to alternation in line broadening. The alternation in the width of hyperfine components in the esr spectra from pyrazine<sup>24</sup> and durosemiquinone anions<sup>23</sup> has also been explained on the basis of this phenomenon. The alternating line-width effects observed in the present case can be satisfactorily explained on the basis of the ion-pair equilibrium model discussed in section VI. When either the lifetime  $\tau_A$  of the A species or  $\tau_B$  of the B species is large compared to the other, an esr spectrum corresponding to the species with the larger lifetime is observed, and in cases where both  $\tau_A$  and  $\tau_B$  are large compared to  $1/\gamma(a_2^H - a_1^H)$ , where  $\gamma$  is the gyromagnetic ratio of the electron, distinct lines from the two different species can be observed. In situation corresponding to  $\tau_A \sim \tau_B = 1/\gamma(a_2^H - a_1^H)$  alternation in the widths of the lines can be observed.<sup>62</sup> Figures 1-3 show spectra corresponding to all these conditions. It is, in fact, possible to calculate the line shapes using this model, and this can be compared with experimental spectra. The result in kinetic data obtained on the system in this manner will be published later.<sup>62</sup>

Although most of our results also could be interpreted in terms of a jumping model, we favor the ion-pair equilibrium model in the present system. In the semiquinone system any intramolecular exchange of the cation should be less favored compared to hydrocarbon anions owing to the strong electrostatic attraction between the oxygen atom and the counterion. Further, our results show that the association between the ion pairs decreases in the order  $\text{Li} > \text{Na} > \text{K}$  for different cations. However, on the basis of an intramolecular exchange model, one should expect the association to be minimum for the lighter Li ion, and the association should increase in the order  $\text{Li} < \text{Na} < \text{K}$ . But it is not possible to lay too much emphasis on this argument to rule out the possibility of the jumping model as a decrease in ionic radius in going from K to Li favors association.

# Chemical Shift Nonequivalence in Proton Magnetic Resonance Spectra of Glycyl Peptides<sup>1</sup>

Vito J. Morlino and R. Bruce Martin

Contribution from the Department of Chemistry, University of Virginia, Charlottesville, Virginia 22901. Received December 22, 1966

**Abstract:** Glycyl methylene splitting due to chemical shift nonequivalence occurs in the proton magnetic resonance spectra of a dozen amino acid-glycyl dipeptides. The magnitude of the splitting does not appear to be correlated with any single structural element and is reduced by the addition of salt or urea and by an increase in temperature. The chemical shift of the high-field glycyl methylene hydrogen in phenylalanylglycine actually moves downfield upon loss of a proton from the ammonium group. Glycyl methylene splitting also occurs in the central glycyl residue of aminoacylglycylglycines, but not in aminoacylglycinamides. Despite the almost exclusive appearance of chemical shift nonequivalence in the dipolar ion form of di- and tripeptides, it is argued that head-to-tail folding is not implied but rather that the oppositely charged termini of the molecules provide a field gradient which acts upon nonequivalent atoms or groups of atoms. Nonbonded interactions of the amino acid side chains with atoms of planar, *trans* amide bonds restrict the number of allowed rotamers about single bonds in the peptide backbone, reducing the averaging effect and resulting in possible augmentation of field gradients at nonequivalent atoms. Examples of chemical shift nonequivalence of methyl group resonances in some derivatives of valine are also reported.

A recent survey of proton magnetic resonance spectra of amino acids and peptides reported splitting of the methylene hydrogens in leucylglycine and in the middle residue of leucylglycylglycine.<sup>2</sup> This splitting was ascribed to preferences for certain unspecified rotamers. Because of the importance of this conclusion for protein conformation and the efficacy of proton magnetic resonance spectroscopy in describing these apparent rotamers, we undertook a pmr study of amino acid-glycine dipeptides for 19 of the 20 (all except asparaginyl) amino acid residues commonly occurring in proteins and for others as well. We find methylene splitting in at least 12 dipeptides and also confirm its existence in tripeptides.

## Experimental Section

The peptides used in this study were the best grade commercially available from Cyclo Chemical Corp., Mann Research Laboratories, and Calbiochem Corp. N-Benzylbutyramide was synthesized from *n*-butyric anhydride and benzylamine following the standard procedure, mp 49–49.5°, lit.<sup>3</sup> 41–44°. The infrared and pmr spectra are consistent for the product. D-Phenylalanyl-L-valine was synthesized from N-carbobenzoxy-D-phenylalanine and L-valine methyl ester hydrochloride, purchased from Cyclo Chemical Corp. The synthesis was carried out in the usual way with N,N-dicyclohexylcarbodiimide.<sup>4</sup> N-Carbobenzoxy-D-phenylalanyl-L-valine methyl ester was prepared in methylene chloride,<sup>5</sup> followed by basic hydrolysis<sup>6</sup> at room temperature and hydrogenolysis in a Parr hydrogenation apparatus. The infrared and pmr spectra are consistent with the products of each step. Carbon, hydrogen, and nitrogen analyses are in excellent agreement with the intermediate and final products.

Proton magnetic resonance spectra were recorded on a Varian A-60 nmr spectrometer equipped with variable-temperature probe.

All spectra were run at room temperature (about 25°) except where noted for leucylglycine. Chemical shifts were generally calculated from the spectra recorded on the 50-cycle sweep width. Sweep widths were frequently calibrated with the Model 200 CD wide-range oscillator and 5512 A electronic counter manufactured by the Hewlett-Packard Co.

In general, 0.3 to 0.5 mmole of the compound was dissolved in 0.5 ml of D<sub>2</sub>O. In cases where the compound failed to dissolve completely, NaOD was added dropwise until the sample was completely dissolved. The pH was measured with a Beckman Model G pH meter equipped with a Beckman No. 40316 one-drop glass electrode. Observed pH meter readings are reported. After the spectrum was recorded at this pH, either NaOD or DCl, depending on the initial pH, was added. The pH was again measured and the spectrum recorded. In all dipeptides, spectra were recorded at high and low pH and at or near to the isoelectric pH. Where possible excess acid or base was added to suppress ionizations. Some peptide spectra were recorded at intermediate pH values. The pH dependence of the chemical shifts of phenylalanylglycine was determined by titrating a 0.9 M, pH 0.5 solution with 3.2 M NaOD and a 0.8 M, pH 11.5 solution with 3.3 M DCl using a Manostat microburet. All chemical shifts are reported in ppm downfield from sodium 3-(trimethylsilyl)-1-propanesulfonate (DSS) as an internal standard.

## Results

In acidic or basic solutions, the glycyl methylene absorption appears as a single resonance line for most of the aminoacylglycines studied in this research. Frequently this resonance peak is broadened or split into an AB quartet in the dipolar ion form of the dipeptide. In the last case a  $\Delta\nu$  and  $J_{AB}$  may be calculated from the spectrum. For these dipeptides the high-field,  $\nu_B$ , and low-field,  $\nu_A$ , chemical shifts in ppm downfield from DSS as an internal standard are recorded in Table I. The dipeptides are listed in approximate order of increasing  $\Delta\nu$ . Values of  $J_{AB}$  vary only slightly from 17.0 to 17.6 cps with a tendency for the greater values to appear in more acidic solutions. The pH values for the solutions recorded in Table I were carefully regulated so that a single charged species predominated. Charges are indicated by beginning with the N terminal ammonium group and ending with the carboxylic acid charge of the glycyl residue. For example, the three charge signs for  $\alpha$ -glutamylglycine refer successively to the N terminal ammonium group,

the  $\gamma$ -carboxylic acid group, and the glycyl carboxylic acid group. In the leucylglycine spectra of the earlier study,<sup>2</sup> one of the peaks designated as an impurity resonance is actually the highest field component of an AB quartet, while the lowest field component occurs at the same field strength as the CH triplet.

<sup>a</sup> In ppm downfield from DSS as internal standard in D<sub>2</sub>O.

<sup>b</sup> Solution insufficiently acid so that this value is a minimum one.

<sup>c</sup> Indication of splitting.

Using a peak width at a half-height of 2 cps or less on the 50-sweep width as the criterion, as well as no indication of the low-intensity outer components of the AB pattern, we observed no splitting of methylene hydrogens in neutral solutions of the following dipeptides and related compounds: glycylglycine, D,L-alanylglycine,  $\beta$ -alanylglycine, L-serylglycine, L-threonylglycine, L-prolylglycine, hydroxy-L-prolylglycine, L-arginylglycine, L-methionylglycine, L-cystinyl-bisglycine, glutathione, acetylglycine, benzoylglycine (basic solution), N-benzylbutyramide (in CDCl<sub>3</sub> where it exhibited a *cis-trans* mixture), sarcosylglycine, glycylsarcosine (exhibits a *cis-trans* mixture), glycyl-L-tyrosine, glycyl-L-leucine, L-valylglycinamide, and L-tyrosylglycinamide. L-Lysylglycine exhibited a peak width of 2.5 cps which was unresolvable. Chemical shift differences of less than about 0.1 ppm would be detected only with difficulty on our instrument. Consideration of these

results and those reported in Table I indicates that no simple single factor, such as electronegativity or the number of substituents on the  $\beta$ -carbon atom, appears to account for the magnitude of splitting.

The magnitude of the methylene splitting in dipolar ion leucylglycine was observed under a variety of solution conditions. The increment of splitting with a decrease in concentration is about 0.017 ppm/mole. Solutions of this dipeptide in 8 *M* urea or 2.5 *M* KCl exhibited a decrease in  $\Delta\nu$  of about 0.04 ppm or 20%. Increasing concentrations of MgCl<sub>2</sub> are more effective on a molar basis than KCl in causing decreases in  $\Delta\nu$ . A solution of dipolar ion leucylglycine in D<sub>2</sub>O at 100 or 120° exhibits a decrease in  $\Delta\nu$  of 0.04 ppm compared to the same solution at room temperature.

Several miscellaneous features of the spectra of the dipeptides recorded in Table I are worth mentioning. Splitting of the glycyl methylene hydrogens in tryptophanylglycine persists into quite acid solutions but finally becomes unanalyzable on our instrument with a peak width at half-height of 4 cps near zero pH. The phenylalanyl part of phenylalanylglycine exhibits an ABX spectrum in basic solutions with  $J_{AX} = 5.1$ ,  $J_{BX} = 8.4$  cps, and  $\Delta\nu_{AB} = 0.125$  ppm. In neutral and acid solutions only an A<sub>2</sub>X type spectrum is obtained. The results are similar to those reported for phenylalanine<sup>7</sup> and other amino acids.<sup>8,9</sup> Upon ionization of the phenolic group in tyrosylglycine, the high-field hydrogens of the A<sub>2</sub>B<sub>2</sub> system of the aromatic ring undergo an upfield shift greater than do the low-field hydrogens, confirming the assignment of the high-field pair as those *ortho* to the hydroxyl group.<sup>10</sup>

The interesting case of phenylalanylglycine, where the methylene resonance is split even in basic solutions, was carefully studied over a range of pH. Individual variations of the low- and high-field proton resonances, A and B, respectively, are shown in Figure 1. A sufficient number of pH values were studied in order to establish that the curves in Figure 1 do not cross. Plateaus occur where one kind of charged species predominates. Upon removal of protons from the carboxylic acid or ammonium groups, the resonance frequency changes in a manner typical of a titration curve. The midpoint of the change in basic solution where the ammonium group is undergoing deprotonation occurs at an observed pH in D<sub>2</sub>O of 7.8 for both A and B hydrogens. A similar analysis is not possible for the region of carboxylic acid ionization because the spectra collapse into a single average line before the extreme acid limit frequencies of the A and B protons may be established. The average value of the chemical shifts of A and B protons moves upfield markedly with deprotonation of the carboxylic acid group and slightly with deprotonation of the ammonium group. These average shifts are similar to those observed for the other dipeptides and for the single peak of the C terminal residue of glycylglycine<sup>11</sup> upon

(11) R. Mathur and R. B. Martin, *J. Phys. Chem.*, **69**, 668 (1965). The chemical shift in this reference for the C terminal residue of dipolar ion glycylglycine should read 1.74(D). Other values are unchanged with the result that the chemical shifts of the pairs of methylene hydrogens in glycylglycine cross twice on going from cationic to anionic species.

equivalent ionizations. In all dipeptides where splitting is observed, the greatest value of  $\Delta\nu$  occurs in solutions of the dipolar ion.

Unequal chemical shift changes are exhibited by the A and B protons as the observed pH is varied in Figure 1. Even more noteworthy is the downfield shift of the high-field B hydrogen on loss of a proton from the ammonium group leaving a negatively charged molecule. This downfield shift of the B hydrogen is just compensated by an upfield shift of the A hydrogen so that the average shift of both hydrogens taken together is slightly upfield by 0.01 ppm on ammonium ionization.

The pronounced difference in behavior between the A and B protons of phenylalanylglycine upon ammonium ionization, along with their continued separate resonances in basic solutions, suggested that a comparison of the resonances of L-phenylalanyl-L-valine with its diastereomeric L,D or D,L dipeptide would be informative. Valine was chosen for the carboxyl terminal residue because there is only one asymmetric carbon atom, and its  $\alpha$ -CH hydrogen resonance is only a doublet and is not split more extensively. Unfortunately after synthesizing the D,L compound, we found the dipolar ion form insufficiently soluble in water. The results are presented in Table II.

Table II. Valyl Resonances of Phenylalanylvalines\*

Charge	L,L		D,L	
	$\alpha$ -CH	Methyls	$\alpha$ -CH	Methyls
+0	4.23	0.97, 0.88	4.18	0.78, 0.67
+-	4.05	0.97, 0.95, 0.86, 0.84	Insoluble	
0-	4.03	0.91, 0.79	3.97	0.71, 0.59

\* In ppm downfield from DSS as an internal standard in  $D_2O$ .

In the cationic and anionic forms, the valyl methyl groups of phenylalanylvaline appear as a doublet split by the  $\beta$ -CH hydrogen with coupling constants of about 6.8 cps. In the dipolar ion form four peaks appear in the methyl region:  $\beta$ -CH splitting yields a similar coupling constant, and there is a second splitting of 0.018 ppm due to chemical shift nonequivalence. The double doublet for methyl resonances also occurs in all three ionic forms of the amino acid valine.<sup>9</sup> The splittings due to chemical shift nonequivalence are 0.017, 0.053, and 0.072 ppm for the cationic, dipolar ion, and anionic forms, respectively, with the high-field methyl group undergoing the largest shift with pH. With no  $\beta$ -CH hydrogen present, the appearance of two peaks in the methyl region of penicillamine ( $\beta$ -mercaptovaline) must be due to chemical shift nonequivalence. The chemical shift differences are 0.06, 0.08, 0.25, and 0.24 ppm for the +1, 0, -1, and -2 charged forms, respectively. Again the high-field methyl peak undergoes the greater shift with pH. Unlike the dipeptides, where the greatest chemical shift nonequivalence for either methyl group or hydrogen splitting occurs in the dipolar ion form, the splitting due to this cause is greater in the most negatively charged species of amino acids.<sup>9</sup> The tripeptide valylglycylglycine exhibits a double doublet for the methyl groups only in basic solution with a splitting due to chemical shift nonequivalence of about 0.02 ppm.

Figure 1. Chemical shift in ppm downfield from DSS as internal standard vs. observed pH meter readings for glycyl methylene protons A and B of 0.75 M phenylalanylglycine in  $D_2O$ . Bullseyes represent two points. Solid points in most acid solutions are average values for unresolved peaks.

A select sample of aminoacylglycylglycine tripeptides was also examined for glycyl methylene splitting in neutral solutions. Consistent with the behavior of the corresponding dipeptides, no splitting was observed in alanylglycylglycine and prolylglycylglycine. A small splitting in the central glycyl residue was observed in valylglycylglycine. Sufficient splitting of the methylene hydrogens in the central glycyl residue to permit analysis was observed in leucylglycylglycine and phenylalanylglycylglycine. Though no splitting of the terminal glycine appeared, the methylene hydrogens of the central glycyl residue exhibited an AB quartet in leucylglycylglycine ( $\nu_A = 4.06$ ,  $\nu_B = 3.98$  ppm) and phenylalanylglycylglycine ( $\nu_A = 3.98$ ,  $\nu_B = 3.88$  ppm). No splitting was observed in either glycyl residue of glycyl-L-leucylglycine.

## Discussion

In order to exhibit chemical shift nonequivalence in nuclear magnetic resonance spectra, two conditions must be met. To be chemical shift nonequivalent, atoms or groups may not be related by a symmetry operation taking into consideration internal motions that are rapid compared to the time scale of an nmr experiment. Secondly, there must exist a sufficient field gradient so that the nonequivalent atoms or groups exhibit chemical shifts resolvable on the instrument employed.

For the L-amino acid-glycine dipeptides of this study, no symmetry element exists along the N-CH<sub>2</sub> bond axis. Even if rotation about the planar and *trans* amide bond were rapid, the methylene hydrogens would still be nonequivalent in these optically active dipeptides and their racemic mixtures. Only if inversion at the asymmetric carbon atom were rapid compared to the nmr

chemical shift would a plane of symmetry include the N-CH<sub>2</sub> bond axis. This explanation for chemical shift nonequivalence arising from molecular dissymmetry does not invoke rotamer preferences about the N-CH<sub>2</sub> or C-CO bonds. If such favored rotamers do exist, they might serve to enhance dissymmetry and hence nonequivalence. The main question posed by the results reported here is, "To what extent are the observed chemical shift differences in glycyl methylene hydrogens augmented or due solely to rotamer preferences?"

Since rotations about all single bonds except the C-N bond in the peptide backbone are rapid, proton magnetic resonance spectra represent weighted average spectra over all rotamers present. Each kind of rotamer gives rise in general to unique shielding at each hydrogen or other atom. If rotamers are equally represented about the whole 360°, then parts of their individual contributions probably cancel and observed chemical shifts represent highly averaged values. In this case contributions to chemical shifts from rotamer preferences are considered insignificant, and any splitting is ascribed to field effects operating on an asymmetric environment.

One of the problems in assessing the importance of rotamer preferences is that potential barriers about C<sub>α</sub>-N and C<sub>α</sub>-CO single bonds in the peptide backbone are not well defined, but appear to be very low, with the result that large numbers of rotamers may be significant. Primarily because of the *trans* conformation of the planar amide group, rotations about single bonds within a given amino acid residue are nearly independent of rotations about neighboring residues in the peptide chain.<sup>12</sup> However, nonbonded interactions of the amino acid side chains with atoms of *trans*, planar amide bonds restrict the number of allowed rotamers even in the case of glycine and markedly more so for larger side chains.<sup>13</sup> In the aminoacylglycines certain rotamers are disadvantaged because of nonbonded interactions, but there remains a considerable arc over which rotamers can occur, especially about the N-CH<sub>2</sub> single bond. There does not seem to be a good correlation between the extent of methylene splitting and the permissible arc over which rotamers can occur. Though large groups with restricted rotamers show chemical shift nonequivalence and appear in Table I, side-chain groups with equally restricted rotamers appear in the list where any splitting was too small to be observed.

Several studies of the physical properties of di-, tri-, tetra-, and pentapeptides have been interpreted to indicate a lesser end-to-end distance in those peptides that contain some D amino acid residues than in those that contain only L residues. This conclusion has been drawn from comparisons of acid ionization constants,<sup>14</sup> transition metal ion interactions,<sup>15</sup> dielectric increments,<sup>16,17</sup> rates of ring closure,<sup>17,18</sup> and proton

magnetic resonance spectra.<sup>19</sup> Not all of these experiments were performed on the dipolar ion form of the peptide; in the last two kinds of measurements the carboxylic acid groups were uncharged.

Examination of nonbonded interactions by use of Courtauld's molecular models indicates that the amino and carboxylic acid groups are brought closer together in L,D than in L,L dipeptides. This result is independent of pH or charge on the terminal groups; the conclusion is forced by consideration of nonbonded interactions alone. Thus the results referred to in the previous paragraph receive a natural explanation so that it is not necessary or desirable to invoke interactions between opposite charges inducing preferred rotamers. Nearly the same rotamer preferences exist in the presence and absence of the dipolar ion charge distribution. No special folded conformation is produced by attraction of oppositely charged ends of the molecule. In an independent study, the chemical shifts produced upon proton ionization in glycine, alanine, and their di- and tripeptides are correlated with the separation along the chain of the measured hydrogen from the protonic center, indicating that head-to-tail folding does not occur to an observable extent in these compounds.<sup>20</sup>

The same nonbonded interactions that force the amino and carboxylate groups to be closer together in the D,L dipeptide also force the side chains to be closer together than in the L,L diastereomer. When one of the side chains is aromatic, the other appears in its shielding cone in the D,L dipeptide with the result that all valyl resonances in Table II for phenylalanylvalines appear at higher field in this diastereomer than in the L,L compound. An identical explanation accounts for the observed higher field resonances in the nonaromatic side chain of the D,L diastereomers of leucyltyrosine<sup>19</sup> and alanyltyrosine<sup>21</sup> compared to the L,L dipeptides.

Counting separately individual charged forms, nearly 100 compounds were examined in this study of chemical shift nonequivalence, yet methylene hydrogen or methyl group nonequivalence was observed only in dipolar ion forms or with aromatic amino acid residues. The lack of correlation between the magnitude of nonequivalence and the allowed rotamers as derived from peptide maps, along with the dependence of rotamer preferences on nonbonded interactions and their independence of charge distribution, suggests that rotamer preferences are not the primary cause for nonequivalence in the di- and tripeptides of this study. Rather the asymmetric carbon provides the potential for chemical shift nonequivalence which is realized by the field gradients produced in dipolar ion forms and by aromatic groups. Any rotamer preferences that occur as a result of nonbonded interactions might serve to heighten nonequivalence.

Methylene splitting also occurs in the central glycyl residues of the dipolar ion forms of the tripeptides leucylglycylglycine and phenylalanylglycylglycine where the charge separation is almost 50% greater than in

dipeptides. The splitting in these two tripeptides is about 40% of that observed in the corresponding dipeptides. Lack of observed methylene splitting in the terminal glycyl residues of tripeptides and either glycyl residue in glycyl-L-leucylglycine is evidently due to their being out of a region of sufficient field gradient.

Temperature dependence of the extent of methylene splitting may in principle distinguish field from rotamer effects since all rotamers should be nearly equally populated at high temperatures, leaving only the averaged field effect to contribute to chemical shift nonequivalence. In the case of leucylglycine an increase in temperature from 25 to 120° reduced the methylene splitting by about 20%. Not even this degree of splitting may be ascribed to rotamer preferences about C-C single bonds because collapse of amide spectra has been observed at less than 100° owing to the onset of rapid rotation about the C-N bond. Because of the small energy differences between potential minima, a very wide temperature range would have to be studied in order to assess quantitatively the importance of rotamers about C-C single bonds. It does not seem possible to separate rotamer from field effects on the basis of the ionic strength dependence of  $\Delta\nu$ . We are unable to determine precisely the extent to which rotamer preferences due to nonbonded interactions contribute to chemical shift nonequivalence, which is due primarily to field effects in the compounds reported in this study.

Methylene or methyl group splitting has also been observed in many compounds that contain no charged groups. Chemical shift nonequivalence has been observed in the nitrogen substituents of uncharged amides with an asymmetric center in the carbonyl substituent.<sup>22</sup>

(22) T. H. Siddall, *J. Phys. Chem.*, **70**, 2249 (1966). Consider, for instance, the methyl groups in compound II.

The presence of an AB quartet of the methylene hydrogens of neopentyl O-methylmandelate<sup>23</sup> demonstrates that nonequivalence may occur across ester as well as amide bonds. Methyl group nonequivalence has been observed in several isopropyl esters.<sup>24</sup> In these compounds polar and aromatic groups may produce field gradients and nonequivalence as do charged and aromatic groups in peptides. The important role of solvent in contributing to the magnitude of chemical shift nonequivalence of solutes has been stressed. In cases where rotamer preferences appear unable to account for the results, greater magnitudes of methylene splitting are observed in media of lower dielectric constants.<sup>25</sup>

Two arguments suggest that the high-field resonance in the aminoacylglycine dipeptides is the one that would remain if the glycyl residue were stereoselectively deuterated so that the deuterium atom appears in the position of the side chain in an L,D or D,L dipeptide. Table II shows that the high-field  $\alpha$ -CH hydrogen resonance of phenylalanylvalines occurs in the D,L diastereomer. In addition, selective deuteration of the methylene group in neopentyl O-methylmandelate such that the product might be considered analogous to a D,L compound results in retention of the high-field resonance.<sup>23</sup> Since both of these examples contain phenyl groups, the conclusion is valid for the compounds with nonaromatic side chains in Table I only if the additional effect of an aromatic group is simply to augment and not to reverse the sign of the chemical shift difference found with aliphatic groups.

## A New Evaluation of Platt's Model for Diatomic Hydrides<sup>1</sup>

W. G. McDugle, Jr.,<sup>2a</sup> and Theodore L. Brown<sup>2b</sup>

*Contribution from the W. A. Noyes Chemical Laboratory, University of Illinois, Urbana, Illinois 61801. Received January 30, 1967*

**Abstract:** Platt's model for diatomic hydrides has been reevaluated using Clementi's Roothaan-Hartree-Fock atomic wave functions. The diatomic hydrides from H<sub>2</sub> through HBr have been treated. The calculated equilibrium internuclear distances are in excellent agreement with experimental values for the united-atom model,  $(Z + 1)^0 \rightarrow (ZH)^0$ , but are too large for the separated-ion model,  $(Z)^-, H^+ \rightarrow (ZH)^0$ . The calculated force constants are also in better agreement with experiment for the united-atom model.

The united-atom model for diatomic hydrides has been the subject of a considerable literature since the initial formulation by Platt in 1950.<sup>2-10</sup> In the

model one begins with a neutral atom of atomic number  $Z + 1$ . The wave function is assumed to have averaged spherical symmetry. A proton is removed from the nucleus and allowed to move out through the fixed

Figure 1. Comparison of experimental internuclear distances (1) with those calculated by the united-atom model (2) and by the separated-ion model (3).

electron distribution. At any distance  $r$  from the nucleus it experiences a force

$$F_H = \frac{-Z + \int_0^r \Psi^* \Psi r^2 dr}{r^2} \quad (1)$$

where  $\Psi$  is the normalized radial function for the initial neutral atom of atomic number  $Z + 1$ . Zero force is achieved when the numerator on the right-hand side is zero. Thus  $r_e$ , the equilibrium internuclear distance, is determined by the relation

$$Z = \int_0^{r_e} \Psi^* \Psi r^2 dr \quad (2)$$

Differentiation of eq 1 gives

$$\frac{\partial F_H}{\partial r} = + \frac{2}{r^3} \left( Z - \int_0^r \Psi^* \Psi r^2 dr \right) + \frac{1}{r^2} \frac{\partial}{\partial r} \left( \int_0^r \Psi^* \Psi r^2 dr \right) \quad (3)$$

This derivative at the equilibrium distance  $r = r_e$  gives the force constant  $k$  for M-H stretching. At  $r = r_e$ , the first term on the right is zero, so

$$k = \left( \frac{\partial F_H}{\partial r} \right)_{r=r_e} = \frac{1}{r_e^2} \frac{\partial}{\partial r} \int_0^{r_e} \Psi^* \Psi r^2 dr = (\Psi^* \Psi)_{r=r_e} \quad (4)$$

Thus, both the equilibrium internuclear distance and stretching force constant are obtainable from a knowledge of the united-atom wave function. Alternatively, one might begin with the separated-ion wave function for M<sup>-</sup> and bring the proton in through the fixed wave function until a point of zero force is reached. Since the model itself is not exact, the two procedures will not in general lead to the same values for  $r_e$  and  $k$ , even if the exact united-atom and separated-ion wave functions were employed.

It has been pointed out that Platt's model violates the quantum mechanical virial theorem, by requiring  $\partial \Psi^* \Psi / \partial r$  to be zero.<sup>5</sup>

This deficiency can be remedied<sup>7</sup> by an appropriate scaling factor  $\eta_0$ , given by

$$\eta_0 = 1 - \frac{1}{U} \int_0^\infty \Psi^* \Psi r dr \quad (5)$$

where  $U$  is the united-atom potential energy, and  $\rho_0$  is determined by the condition

$$Z = \int_0^\infty \Psi^* \Psi r^2 dr \quad (6)$$

Figure 2. Comparison of experimental force constants (1) with those calculated by the united-atom model (2) and by the separated-ion model (3).

The equilibrium internuclear distance is then given by  $r_e = \rho_0 / \eta_0$ . The scaled force constant is given by the relationship

$$k = \eta_0^4 \Psi^* \Psi (\eta_0 - \rho_0^2 \Psi^* \Psi / U)^{-1} \quad (7)$$

In this expression it is assumed that the united-atom wave function satisfies the atomic virial theorem, which is in fact the case in the results presented here. Equation 7 approaches Platt's expression (eq 4) as  $\eta_0 \rightarrow 1$ . Equation 5 requires amendment for the separated-ion model; the correct expressions are given by Hall and Rees.<sup>7</sup>

Despite a perennial interest in Platt's model, and numerous considerations of its significance and limitations, it has not as yet been thoroughly tested in terms of an extensive set of accurate atomic and ionic wave functions. The recent appearance of such wave functions makes adequate testing feasible. We present herein the application of Platt's model for both united-atom and separated-ion wave functions to the extensive set of atomic and ionic wave functions of Clementi<sup>11</sup> for the elements He through Kr, both with and without scaling. In the following paper,<sup>12</sup> the model is extended to a consideration of the transition metal carbonyl hydrides.

## Computation

The atomic and ionic wave functions employed in our calculations are the analytical Hartree-Fock functions developed by Clementi.<sup>11</sup> The total wave functions are expressed as sums of several Slater determinants which are in turn antisymmetrized products of one-electron spin orbitals. The orbital functions are obtained by solving the Roothaan-Hartree-Fock equations.<sup>13</sup> The orbitals which make up the Slater determinants are of the form

$$\phi_{i\lambda\alpha} = \sum_p \chi_{p\lambda\alpha} C_{i\lambda p}$$

in which  $\lambda$  is a symmetry index (quantum number  $l$ )

<sup>a</sup> Atomic number of corresponding united atom. <sup>b</sup> In units of 10<sup>4</sup> dynes/cm.  $k$  is calculated from  $\omega_e$  values<sup>g</sup> (i.e., it is corrected for anharmonicity) except where noted. <sup>c</sup> In angstroms. <sup>d</sup> The equilibrium values given here are  $r_0$  as defined in footnote g. The  $r_0$  values differ very little from the  $r_e$  values. For example,  $r_0$  for NiH is 1.47 Å, whereas  $r_e$  is 1.49 Å. <sup>e</sup> Data taken from Tables de Constantes et Données Numeriques, Vol. 4, B. Rosen, Ed., Hermann & Cie, Depositaires, Paris, 1951. <sup>f</sup> Value estimated by J. L. Margrave, *J. Phys. Chem.*, **58**, 258 (1954). <sup>g</sup> G. Herzberg, "Molecular Spectra and Molecular Structure. 1. Spectra of Diatomic Molecules," D. Van Nostrand Co., Inc., Princeton, N. J., 1950. <sup>h</sup> B. Klemm and E. Werhagen, *Arkiv Fysik*, **6**, 359 (1953). <sup>i</sup> Calculated from  $\Delta G_{1/2}$  values as defined in footnote g. These values are uncorrected for anharmonicity in the vibrations. The correction is usually small and results in a 2% error at most in  $k$ . <sup>j</sup> There are two observed states. In the other,  $r_0 = 1.48$  Å. <sup>k</sup> The force constants are calculated from  $\omega_e$  values which are not well known.

and  $\alpha$  is the subspecies index which labels the individual members of the degenerate set transforming according to the  $\lambda$  representation. The subscript  $p$  refers to the  $p$ th basis function of symmetry  $\lambda$ . The  $\chi$ 's are Slater-type orbitals with integral quantum numbers

$$\chi_{p\lambda\alpha}(r, \nu, \varphi) = R_{\lambda p}(r) Y_{\lambda\alpha}(\nu, \varphi)$$

We are concerned with the radial part of the orbitals

$$R_{\lambda p} = [(2n_{\lambda p})!]^{-1/2} (2\zeta_{\lambda p})^{n_{\lambda p} + 1/2} r^{n_{\lambda p} - 1} \exp(-\zeta_{\lambda p} r) \quad (8)$$

The size of the basis set employed in obtaining each  $\vartheta_{\lambda\alpha}$  varies. In all cases, however, the resulting atomic wave functions are very good approximations to the Hartree-Fock limit and represent the most accurate extensive set of wave functions presently available.

The solutions to eq 2 or 6 and 5 are found by numerical integration of the appropriate expansions at various values for  $r$ . The values for  $k$ , from eq 2 or 7, are readily computed once  $\eta_0$ ,  $\rho_0$ , and  $r_e$  are known ( $U$  is given by Clementi). The results for the binary hydrides are

given in Table I for the united-atom and separated-ion models. (Scaling was not included in the separated-ion calculations because the scale factor is essentially unity in all cases.)

The internuclear M-H distances calculated by the two methods are compared with the experimental results in Figure 1.

## Discussion

It is quite evident from Table I and Figure 1 that the united-atom model yields very good values for the internuclear distance. Discounting the results for the first two or three elements, to which the model can hardly be expected to apply, the error seldom exceeds 5%. This is a particularly pleasing result, since Platt was unable to obtain satisfactory values for  $r_e$  with the atomic wave functions available to him. It is also noteworthy that the united-atom model gives much better results for  $r_e$  than the separated-ion model. It has not been obvious until now that this would prove

to be the case, and, in fact, arguments have been advanced<sup>7</sup> for the superiority of the latter model. The united-atom model is also clearly more successful in calculating the force constants (Figure 2). The general trend of force constant within each horizontal row is reproduced quite well. The errors in the calculated values for this observable are relatively much larger than for the internuclear distance. The reasons for this are perhaps most evident when the problem is viewed in terms of the Hellmann-Feynman theorem. The expectation value for internuclear distance is dependent on the equilibrium wave function, for which the Hartree-Fock atomic wave function for the neutral atom of  $Z + 1$  nuclear charge is apparently a good approximation. The stretching-force constant, however, involves an expression of the form<sup>8</sup>

$$k = \frac{2Z}{r^3} + \int \Psi^* \Psi \frac{\partial^2 V_{ne}}{\partial r^2} d\tau + \int \frac{\partial(\Psi^* \Psi)}{\partial r} \frac{\partial V_{ne}}{\partial r} d\tau \quad (9)$$

where  $V_{ne}$  is the nuclear-electronic attraction operator,  $V_{ne} = \sum_a -1/r_{aH}$ , where the sum is over all electrons. The last term in this equation is a measure of relaxation in the electron distribution accompanying nuclear motion. In the Platt model this term is assumed to be zero. Only a fortunate cancellation with another large term of opposite sign can yield a satisfactory value for  $k$ . Such a cancellation does apparently exist, but  $k$  is nevertheless not as accurately predicted as  $r_e$ .

## Application of Platt's Model for Diatomic Hydrides to Metal Carbonyl Hydrides<sup>1</sup>

W. G. McDugle, Jr., A. F. Schreiner, and Theodore L. Brown

*Contribution from the W. A. Noyes Chemical Laboratory, University of Illinois, Urbana, Illinois 61801. Received January 30, 1967*

**Abstract:** Platt's united-atom model for diatomic hydrides is extended to metal carbonyl hydrides. The equations are the same as for the diatomic case, except that a classical approximation is employed to take account of net charge which may be present on the CO groups. The model provides a simple picture for metal-hydrogen bonding and accounts nicely for the similarity in M-H stretching frequency with the corresponding diatomic metal hydride. The following values are estimated for equilibrium M-H distances:  $\text{Mn}(\text{CO})_5\text{H}$ , 1.60 Å;  $\text{Co}(\text{CO})_4\text{H}$ , 1.40 Å;  $\text{Fe}(\text{CO})_4\text{H}^-$ , 1.40 Å;  $\text{Cr}(\text{CO})_5\text{H}^-$ , 1.50 Å.

The transition metal carbonyl hydrides are an interesting and varied group of compounds.<sup>2,3</sup> The purpose of the present contribution is to consider the metal-hydrogen bond in terms of an extension of Platt's model for diatomic hydrides.<sup>4,5</sup>

The metal carbonyl hydrides can be considered to derive in principle from a parent metal carbonyl molecule or ion by abstraction of a proton from the nucleus of the central metal atom.<sup>6</sup> The abstracted proton is allowed to move out through an electronic environment which is forced to remain unchanged, except for relatively minor C-M-C bond angle changes. When the nuclear-electronic attractive forces on the proton equal the proton-nuclear repulsive forces, the proton comes to rest. Some examples of the process envisaged are

If it is assumed that the proton exerts a slight net repulsive effect on the CO groups, it may then be expected to occupy somewhat less space than the surrounding CO groups. Thus in  $\text{Mn}(\text{CO})_5\text{H}$  the axial-radial C-Mn-C angle is  $97^\circ$ ;<sup>7</sup> the average CO-CO distance is only slightly less than in the parent  $\text{Fe}(\text{CO})_5$ .

The carbonyl hydride formation described above is an isoelectronic process and may be considered in terms of the Hellmann-Feynman theorem. Employing the integral form of this theorem,<sup>8</sup> we label the parent carbonyl compounds as the X state and the carbonyl hydride in its equilibrium configuration as the Y state. Then the difference in energy,  $\Delta W$ , exclusive of the change in nuclear energy, is given by

$$W = \Delta V_{nn} + \frac{N}{S} \int \Psi_X H'(1) \Psi_Y d\tau \quad (1)$$

$$W = \Delta V_{nn} + \frac{N}{S} \int \rho_{XY}(1) H'(1) d\tau(1)$$

The first term on the right represents the difference in the classical nuclear-nuclear potential,  $\sum_{jk} Z_j Z_k / r_{jk}$ , where  $Z_j$  and  $Z_k$  are the charges on nuclei  $j$  and  $k$ , and  $r_{jk}$  is the internuclear distance. The normalized transi-

tion density  $\rho_{XY}(1)$  is given by

$$\rho_{XY}(1) = \frac{N}{S} \int \Psi_X(1) \Psi_Y(1) d\tau(2) d\tau(3) \dots d\tau(N)$$

$$S = \int \Psi_X(1, 2, \dots, N) \Psi_Y(1, 2, \dots, N) d\tau(1) \dots d\tau(N)$$

The perturbation Hamiltonian  $H'$  is given by

$$H'(1) = V_{ne}^Y(1) - V_{ne}^X(1)$$

The elucidation of these expressions is greatly simplified if it is assumed that all interactions of the CO groups with one another and with the central metal are unchanged in the process  $X \rightarrow Y$ . This means that only the term  $\Sigma Z_{jH}/r_{jH}$  remains in  $\Delta V_{nn}$ , and that  $H'(1) = \Sigma_{\alpha} (-1/r_{H\alpha})$ , where  $\alpha$  runs over all electrons. Although this assumption may seem a bit drastic, it is quite reasonable in terms of what data are available. The CO stretching frequencies in the infrared-active modes, for example, are not changed drastically, as the comparisons in Table I show. The CO frequencies in the hydride are very little different from those in the parent carbonyl, whereas they are much lower in the anion corresponding to complete removal of the proton.

<sup>a</sup> W. F. Edgell, J. Huff, J. Thomas, H. Lehman, C. Angell, and G. Asato, *J. Am. Chem. Soc.*, **82**, 1254 (1960). <sup>b</sup> P. S. Braterman, R. W. Harrill, and H. D. Kaesz, submitted for publication.

From this point it is possible to make still further simplifying assumptions. The common view of the neutral metal carbonyls is that the central metal atom carries essentially zero charge. Although it is difficult to gather definitive evidence on this point, the isomer shift in the Mössbauer spectrum<sup>9</sup> of  $\text{Fe}(\text{CO})_5$  and related compounds is consistent with near-zero charge on the metal. The appearance potentials of neutral as well as positively charged metal carbonyl fragments parallel the ionization potentials of the metal atoms or ions of corresponding charge remarkably well,<sup>10</sup> a further indication that the over-all charge of the metal carbonyl moiety is a measure of the metal atom charge. It is possible then to consider that the nuclear-nuclear and nuclear-electronic components of  $\Delta W$  which involve the C and O nuclei and electron density localized in the CO regions cancel for the proton. There remains just the interaction with the central nucleus and transition density centered thereon

$$\Delta W = \frac{Z}{r_{MH}} - \frac{N}{S} \int \rho_{XY}^M(1) \frac{1}{r} d\tau(1) \quad (2)$$

(9) R. H. Herber, R. B. King, and G. K. Wertheim, *Inorg. Chem.*, **3**, 101 (1964).

(10) R. E. Winters and R. W. Kiser, *J. Phys. Chem.*, **70**, 1680 (1966).

If that part of  $\Psi$  centered on M is assumed to be invariant to the  $X \rightarrow Y$  process, then  $\rho_{XY}$  becomes simply the one-electron charge density on M,  $\rho_M(1)$

$$\Delta W = \frac{Z}{r_{MH}} - \int \rho_M(1) \frac{1}{r} d\tau(1) \quad (3)$$

We desire  $\partial \Delta W / \partial r_{MH} = 0$  at the equilibrium CO distance, which gives

$$\frac{Z}{r_e^2} = \int_0^{\infty} \frac{\rho_M^{(1)}(r)}{r^2} d\tau(1) \quad (4)$$

If  $\rho_M$  is spherically symmetric, this is just Platt's model for a diatomic hydride. The force constant follows in the usual way. Although the net charge in the metal carbonyl may be zero as assumed, it is of interest to explore the consequences of the assumption that it is not. We assume again that the CO-CO and CO-M interactions are the same in the X and Y states. Further, the proton-electron and proton-nuclear interactions with the CO groups are assumed to yield a net potential energy,  $\Sigma_i S_i / r_{iH}$ , where  $S_i$  is the net charge on the  $i$ th CO group, and  $r_{iH}$  is the distance from the proton to the center of the  $i$ th CO bond. Thus, if the metal is assumed to have a net charge of  $-1$  in  $\text{Mn}(\text{CO})_5\text{H}$ ,  $+0.20$  unit of charge may be assigned to each CO group. Alternatively, it might be assumed that the axial CO group has a different net charge than the radial, etc. The components of  $\Delta W$  relating to the central atom and electron density centered there remain unchanged. Then

$$\Delta W = \frac{Z}{r_{MH}} - \int \rho_M \frac{1}{r} d\tau + \sum_i \frac{S_i}{r_{iH}} \quad (5)$$

$$\frac{\partial \Delta W}{\partial r_{MH}} = 0 = \frac{-Z}{r_e^2} + \int \frac{\rho_M}{r^2} d\tau - \sum_i \frac{S_i \cos \theta_{iH}}{r_{iH}^2} \quad (6)$$

The charge density  $\rho_M$  in eq 6 is that appropriate to the metal atom in a zero or nonzero charge state, depending on  $\Sigma S_i$  and the total net charge on the parent carbonyl. Aside from assignment of charge state, there is the problem of choosing the appropriate configuration, which may be different from that in the free metal of the same charge. An attempt has been made to evaluate the sensitivity of the results to this variable. It should be pointed out that the scaling procedure applied to diatomic M-H systems<sup>6,11</sup> has been employed in the same manner as before.

A few qualitative conclusions can be drawn immediately from the proposed model. If the charge on the metal in the parent carbonyl is near zero, then it follows that the metal-hydrogen bond should possess about the same stretching force constant and equilibrium nuclear distance as in the corresponding diatomic hydride. The evidence regarding distances is somewhat tenuous at present (*vide infra*), but the force constant results are qualitatively as expected, as evidenced by the comparisons of observed metal-hydrogen stretching frequencies given in Table II.

## Results

from zero, it has been assumed that the charge of opposite sign is distributed equally among the five CO groups. The results were not affected by assuming that the axial CO group carries a slightly different charge than the radial. The bond angles and distances observed in solid  $\text{HMn(CO)}_6$ <sup>7</sup> were employed in the calculation. The resulting equilibrium Mn-H distance as a function of metal charge is shown as the solid line in Figure 1. There is only one other configuration available for testing, namely  $4s^03d^7$  for  $\text{Fe}^+$ , for which the calculated equilibrium Mn-H distance is shown as the single point on the figure. This configuration represents an unlikely extreme in terms of s character. It is generally assumed from theoretical considerations that the first-row transition metals do employ considerable 4s orbital character in metal carbonyl compounds. The solid curve in Figure 1 is therefore probably satisfactory from the standpoint of s orbital character. The effect of 4p character on the equilibrium Mn-H distance is an important question, which we cannot test for a lack of the appropriate atomic wave functions. Although 4p orbital functions of high accuracy are not available for the first-row transition elements, it is quite clear that the 4p charge densities lie outside the 3d. Richardson and co-workers<sup>14</sup> report that in the neutral atoms the 3d distribution completely screens nuclear charge from the 4p, to

(14) J. W. Richardson, R. R. Powell, and W. C. Nieuwpoort, *J. Chem. Phys.*, **38**, 796 (1963).

Figure 2. Calculated equilibrium distance and stretching frequency for the Co-H bond in  $\text{HCo(CO)}_4$ , as a function of metal charge.

within 1%. We may state with confidence, therefore, that the assumed  $4s^23d^n$  configuration will lead to a lower bound estimate of the Mn-H distance for the model chosen. Part of the error resulting from failure to include 4p occupation is cancelled by the assumption of a full two-electron occupation of the 4s.<sup>15</sup> The 4s and 4p have similar radial charge-density dependences.

The dotted line shows the calculated Mn-H stretching frequency, in the harmonic oscillator approximation, as a function of metal charge, for the assumed  $4s^23d^n$  configurations. As the metal charge becomes more negative, there is an asymptotic approach to a frequency of about 1500  $\text{cm}^{-1}$ , somewhat below the observed frequency of 1775  $\text{cm}^{-1}$ . Frequency decreases quite rapidly with increase in charge above zero. The model is in best accord, therefore, with a metal charge of about -0.5; the predicted Mn-H stretching frequency is in the range 1350 to 1450  $\text{cm}^{-1}$ ; and the predicted Mn-H bond distance is  $1.60 \pm 0.07$  Å.

**Co(CO)<sub>4</sub>H.** The procedure described above was followed also for  $\text{Co(CO)}_4\text{H}$ . Unfortunately, the only configuration of  $\text{Ni}^-$  for which the wave function is available is  $4s^13d^{10}$ ; this was used along with the wave function of the  $4s^23d^8$  and  $4s^23d^7$  configurations for  $\text{Ni}$  and  $\text{Ni}^+$ , respectively. The results are graphed in Figure 2. For  $\text{Ni}^+$  the configuration  $4s^03d^9$  is also available. The result of using the wave function for this configuration is shown as the single point. We take half the difference between this point and the point corresponding to the  $4s^23d^7$  configuration as a correction to the  $4s^13d^{10}$  point at -1 charge, to make it correspond approximately to a  $4s^23d^9$  configuration. This point is used in constructing the solid line in Figure 2.

The calculated equilibrium Co-H distance was found to be quite insensitive to the assumed C-Co-C angles. The data are shown for tetrahedral disposition of the CO groups. Variation of up to  $10^\circ$  in the H-Co-C angles produced a change of less than 0.02 Å in the calculated Co-H distance, even when the charge on the metal is assumed to be +1 or -1.

(15) An extensive approximate Roothaan SCF MO calculation on  $\text{Ni(CO)}_4$ , using approximate SCF metal atomic orbitals<sup>14</sup> in the basis set, has been carried out by W. C. Nieuwpoort, *Philips Res. Rept. Suppl.*, **6**, 1 (1965). He obtains a net metal charge, based on a conventional population analysis, of -1. The total Ni orbital populations are  $4s^0.44p^{1.03}d^{8.5}$ .

Figure 3. Calculated equilibrium distance and stretching frequency for the Fe-H bond in  $\text{HFe}(\text{CO})_4^-$ , as a function of metal charge.

Figure 4. Calculated equilibrium distance and stretching frequency for the Cr-H bond in  $\text{HCr}(\text{CO})_5^-$ , as a function of metal charge.

The variation in Co-H stretching frequency as a function of assumed metal charge, for the  $4s^23d^8$  configuration is shown as the dashed line in Figure 2. The value  $-1$  charge is only approximate, since the  $4s^23d^9$  wave function is not available. The observed frequency intersects the line at a metal charge of about  $-0.5$ . For this charge the equilibrium Co-H bond distance is calculated to be about  $1.40 \pm 0.1$  Å.

Wave functions for  $4s^23d^8$  configurations of  $\text{Co}^-$ ,  $\text{Co}^0$ , and  $\text{Co}^+$  are available. The results of the calculations are as shown in Figure 3. The observed Fe-H stretching frequency is approached in the calculations for a rather negative charge on the metal, the range from  $-0.5$  to  $-1$ . The calculated Fe-H frequency based on this range of charge is  $1.40 \pm 0.05$  Å.  $\text{Cr}(\text{CO})_6$  and  $\text{HCr}_2(\text{CO})_{10}^-$ . The calculations for  $(\text{CO})_6^-$  were carried out as described above for the other cases, using Mn wave functions for  $4s^23d^8$  configurations (Figure 4). For a metal charge of about  $+1/5$ , the Cr-H frequency is calculated as  $1600 \text{ cm}^{-1}$ , Cr-H distance as  $1.50 \pm 0.05$  Å.

Certain aspects of the structure of  $\text{HCr}_2(\text{CO})_{10}^-$  have recently been described.<sup>16</sup> The hydrogen is presumably located along the Cr-Cr axis and separates  $\text{Cr}(\text{CO})_5$  units. If we assume that each unit carries a  $-0.5$  charge, the charge on the Cr in  $\text{HCr}_2(\text{CO})_{10}^-$  would be slightly less negative, by perhaps  $0.25$  e, than  $\text{Cr}(\text{CO})_5^-$ . Assuming that the charge on the Cr in  $(\text{CO})_5^-$  is  $-0.5$ , a Cr-H distance of  $1.54$  Å is estimated from Figure 4. This leads to a predicted Cr-Cr distance of about  $3.1$  Å, as compared with the experimental value of  $3.41$  Å.<sup>16</sup> The comparison is rather close, but the agreement is encouraging.

## Discussion

There is an unfortunate paucity of data regarding metal-hydrogen distances in metal carbonyl hydrides.

L. B. Handy, P. M. Treichel, L. F. Dahl, and R. G. Hayter, *J. Chem. Soc.*, **88**, 366 (1966).

The results obtained here are in good agreement with expectations based on somewhat empirical covalent radii.<sup>16</sup> Thus a value of about  $1.65$  is expected for the Mn-H distance, as compared with our calculated value of  $1.60 \pm 0.07$  Å.

The only experimental data which relate directly to the M-H distances are the broad-line proton nmr studies of Farrar, Davison, *et al.*<sup>17</sup> These authors conclude that the Mn-H distance in  $\text{HMn}(\text{CO})_5$  is  $1.28$  Å. The Co-H distance in  $\text{HCo}(\text{CO})_4$  is estimated on the basis of line-shape data as  $1.2 \pm 0.1$  Å.<sup>18</sup>

Both these results are shorter than the estimates from the present calculations. No reasonable modification which retains the simplicity of the model could appreciably shorten the calculated M-H distances. Indeed, the calculated values are probably lower bounds, in view of our neglect of the  $4p$  orbital occupations.

Even if the estimates of metal-hydrogen distances from the nmr studies are subsequently corroborated by neutron diffraction or other data, the results obtained are quite good for such a simple model. The approach is of value in suggesting how the transition metal hydride structures relate to known organometallic structures.<sup>2,19</sup> It provides a nice rationale for the observation that the M-H stretching frequencies are close to those for the corresponding diatomic metal hydrides. Extension to calculation of other expectation values, notably chemical shift<sup>20</sup> and electric field gradient,<sup>21</sup> would not be difficult.

# The $^{19}\text{F}$ Nuclear Magnetic Resonance Spectra of Oxygen Fluorides<sup>1</sup>

J. W. Nebgen, F. I. Metz, and W. B. Rose

Contribution from Midwest Research Institute, Kansas City, Missouri 64110.

Received November 23, 1966

**Abstract:** The  $^{19}\text{F}$  nuclear magnetic resonance (nmr) spectra of liquid  $\text{F}_2$ ,  $\text{OF}_2$ ,  $\text{O}_2\text{F}_2$ , and  $\text{O}_3\text{F}_2$  are presented. The shifts of  $\text{O}_2\text{F}_2$  and  $\text{O}_3\text{F}_2$  are the furthest downfield of any simple fluorine compound yet reported. The structural implications of these shifts are discussed. A model for  $\text{O}_3\text{F}_2$  is postulated in which this species is made up of  $\text{O}_2\text{F}_2$  and "interstitial"  $\text{O}_2$ .

The nuclear magnetic resonance (nmr) spectra of the series  $\text{F}_2$ ,  $\text{OF}_2$ ,  $\text{O}_2\text{F}_2$ , and  $\text{O}_3\text{F}_2$  have been observed. The shifts observed for  $\text{O}_2\text{F}_2$  and  $\text{O}_3\text{F}_2$  represent the least shielded of any fluorine compounds yet reported. The vast difference in chemical shift of  $\text{O}_2\text{F}_2$  and  $\text{O}_3\text{F}_2$  indicates that the fluorine nuclei (hence fluorine-oxygen bonding) are considerably different in  $\text{O}_2\text{F}_2$  and  $\text{O}_3\text{F}_2$  as compared to  $\text{OF}_2$ . A summary of chemical shifts is presented in Table I. The  $\text{O}_3\text{F}_2$  is given in quotations, since there is some uncertainty about the reality of the compound. This uncertainty will be discussed in some detail later.

Table I.  $^{19}\text{F}$  Nmr Shifts for Liquid  $\text{F}_2$ ,  $\text{OF}_2$ ,  $\text{O}_2\text{F}_2$ , and  $\text{O}_3\text{F}_2$  ( $\text{CFCl}_3$  reference)

Compound	Shift, ppm
$\text{F}_2$ (77°K)	$-422 \pm 1$
$\text{OF}_2$ (77°K)	$-249 \pm 1$
$\text{O}_2\text{F}_2$ (145°K)	$-865 \pm 1$
" $\text{O}_3\text{F}_2$ " (<145°K)	$-877 \pm 5$

The nmr spectra of liquid  $\text{F}_2$  and  $\text{OF}_2$  have been reported by Nebgen, Rose, and Metz.<sup>2a</sup> Recently Lawrence, Ogden, and Turner<sup>2b</sup> have reported the  $^{19}\text{F}$  nmr spectrum of  $\text{O}_2\text{F}_2$  in  $\text{CF}_3\text{Cl}$  to be at  $-825 \pm 10$  ppm with respect to a Freon 11 ( $\text{CFCl}_3$ ) reference. This signal is about 40 ppm higher than our observation in the neat liquid. No open literature reports of the  $^{19}\text{F}$  nmr signal in  $\text{O}_3\text{F}_2$  are available; however, Solomon and co-workers have observed the  $^{17}\text{O}$  and  $^{19}\text{F}$  nmr signals from  $\text{O}_3\text{F}_2$ .<sup>3</sup> Their observations on the  $^{19}\text{F}$  nmr spectrum of  $\text{O}_3\text{F}_2$  at temperatures near 145°K are identical with ours. Solomon, *et al.*, had better means of temperature control than we, and hence could study the chemical shift of  $\text{O}_3\text{F}_2$  as a function of temperature. They found that the shift was very far downfield ( $-1900$  ppm at 85°K) and moved upfield to  $-868$  ppm at 145°K. The  $-868$ -ppm peak is that of  $\text{O}_2\text{F}_2$ . This upfield shift with temperature is the same as we observed in  $\text{O}_3\text{F}_2$ .

## Experimental Section

Commercially available  $\text{F}_2$  (The Matheson Co., Inc.) and  $\text{OF}_2$  (General Chemical Division, Allied Chemical Corp.) were used in the studies. Prior to sampling, each of the compounds was passed through a hydrogen fluoride trap. The  $\text{OF}_2$  contained additional impurities (primarily oxygen) not removed by the HF trap and was further purified by gas chromatography.

The  $\text{O}_2\text{F}_2$  and  $\text{O}_3\text{F}_2$  were prepared using the usual discharge techniques. The reaction vessel is similar to that used by Streng,<sup>4</sup> with the exception that the whole vessel is made of Pyrex. A standard taper male connection is placed at the bottom of the reactor to attach sample tubes. The sample tubes were 2-mm capillaries for use in a constant-temperature nmr dewar.<sup>5</sup>

The nmr spectra of the liquid  $\text{F}_2$  and  $\text{OF}_2$  samples were recorded at 77°K on a Varian Associates HA-100 nmr spectrometer operating at a frequency of 94.075 Mc. That of  $\text{O}_2\text{F}_2$  was recorded at 145°K using liquid  $\text{CF}_3\text{Cl}$  as a cryogenic. The nmr signals were externally referenced to the  $^{19}\text{F}$  signal from  $\text{CFCl}_3$ . Referencing was accomplished by carefully removing the sample from the magnet probe and replacing it with the reference material. This transfer occurred while the magnetic field was being swept at a constant rate. No significant variations in the field sweep rate were observed in the transfer operation. Each sample was scanned several times, and the transfer done at different intervals during the field sweep.

The spectrum of  $\text{O}_3\text{F}_2$  required a different technique. After scanning several samples of  $\text{O}_2\text{F}_2$ , it became apparent that the recorded signal was due to  $\text{O}_2\text{F}_2$  which is the major decomposition product. In other words,  $\text{O}_3\text{F}_2$  is not sufficiently stable to permit scanning over the period of time required for a recorder trace. To circumvent this stability problem, the oscilloscope display of the nmr signals was used.

The signal from pure  $\text{O}_2\text{F}_2$  was centered on the scope of the HA-100. The  $\text{O}_2\text{F}_2$  "reference" was removed and replaced with a sample of  $\text{O}_3\text{F}_2$  at 77°K. The liquid nitrogen in the nmr dewar was then replaced with liquid  $\text{CF}_3\text{Cl}$  and the scope signal monitored with time. After 1 min, the sample began to melt and a weak signal appeared on the scope downfield from the  $\text{O}_2\text{F}_2$  "reference." Within 2 min, this signal was fairly well defined. During the third minute the signal shifted, and at 3 min reappeared at the same spot where the  $\text{O}_2\text{F}_2$  "reference" signal was located. The experiment was reproduced several times, and we feel confident that the signals observed in the first 2 min represent the nmr peak for  $\text{O}_3\text{F}_2$  which then rapidly decomposes to  $\text{O}_2\text{F}_2$  and  $\text{O}_2$ . The time sequence of spectra, taken from Polaroid photographs of the events, is shown in Figure 1.

## Discussion

The nmr spectra of  $\text{F}_2$ ,  $\text{OF}_2$ ,  $\text{O}_2\text{F}_2$ , and  $\text{O}_3\text{F}_2$  clearly indicate that the  $^{19}\text{F}$  nuclei in the latter two are very different from those in the former two. Thus some fundamental structural considerations are in order.

Linnett<sup>6</sup> has discussed a novel approach to electronic structure of molecules using the concept of two

Figure 1.  $^{19}\text{F}$  nuclear magnetic resonance spectra of " $\text{O}_3\text{F}_2$ " as a function of time.

four electrons around a nucleus rather than the Lewis structures of four sets of two electrons. Postulated structures for  $\text{F}_2$ ,  $\text{OF}_2$ , and  $\text{O}_3\text{F}_2$  structures are presented in Figure 2. In these structures, a heavy line indicates two electrons occupying opposite spins occupying the same spatial orbital; a light line indicates two electrons on the same orbital between the same pair of atoms) having opposite spins but not occupying the same orbital; and crosses and circles represent electrons of differing spin in a particular region. Recently Spratley and Pimentel<sup>7</sup> have proposed a molecular orbital treatment of fluorine bonding which results in essentially the same structure for  $\text{O}_3\text{F}_2$ .

The structures of  $\text{F}_2$ ,  $\text{OF}_2$ , and  $\text{O}_3\text{F}_2$  can be well visualized, and hence their  $^{19}\text{F}$  nmr signals can be interpreted in accordance with their structures. The "one-electron" bond model in  $\text{O}_3\text{F}_2$  would result in a fluorine nucleus which has a very low shielding constant and is consistent with the  $^{19}\text{F}$  nmr spectrum. The theory of  $^{19}\text{F}$  nmr shifts as proposed by Saika and Slichter<sup>8</sup> is inadequate to explain the shift in  $\text{O}_3\text{F}_2$ . The inadequacy lies in the fact that the theory is consistent with "normal" fluorine bonds and does not treat the "one-electron" fluorine bonds as postulated by Linnett.

Recently, Baker, Anderson, and Ramsey<sup>9</sup> have discussed nuclear magnetic antishielding of  $^{19}\text{F}$  nuclei. Their calculation of antishielding is based on the combination of molecular beam data on spin-rotational transitions in molecules with chemical shift data. The combination is used to calculate the paramagnetic contribution to the nuclear shielding constant in the Ramsey equation.<sup>10</sup>

The observations of the  $^{19}\text{F}$  nmr signal from  $\text{O}_3\text{F}_2$  indicate that considerable antishielding exists in the molecule. Furthermore, we suggest that the antishielding is associated with the long O-F bond in  $\text{O}_3\text{F}_2$  (1.58 Å for  $\text{O}_3\text{F}_2$  compared to 1.41 Å for  $\text{OF}_2$ ). This suggestion then leads to the possibility that antishielding

Figure 2. Linnett structures for  $\text{F}_2$ ,  $\text{OF}_2$ , and  $\text{O}_3\text{F}_2$ .

shielding may be related in some way to the overlap of the fluorine atom p orbital with the antibonding orbitals in the oxygen molecule as postulated by Spratley and Pimentel.<sup>7</sup>

Structural considerations for  $\text{O}_3\text{F}_2$  are not as straightforward, since supporting data from infrared and microwave are not available as they are for  $\text{O}_2\text{F}_2$ .<sup>12</sup> In order to interpret the nmr shifts observed, three assumptions about the  $\text{O}_3\text{F}_2$  molecule must be made. The first assumption is that  $\text{O}_3\text{F}_2$  is structurally similar to  $\text{O}_2\text{F}_2$ ; that is to say that the fluorine-oxygen bond is essentially a "one-electron" bond. Secondly, the fluorine nuclei in  $\text{O}_3\text{F}_2$  are equivalent. This assumption is based on the observation that the intensity which is observed in the  $\text{O}_3\text{F}_2$  signal is about the same as that observed in the  $\text{O}_2\text{F}_2$  decomposition product indicating that the same number of fluorine nuclei are giving rise to both signals. The third assumption is that  $\text{O}_3\text{F}_2$  should have a ready route back to an  $\text{O}_2\text{F}_2$  decomposition product. This assumption explains the ready decomposition of  $\text{O}_3\text{F}_2$  to  $\text{O}_2\text{F}_2$  and the lack of  $\text{OF}_2$  and  $\text{F}_2$  as decomposition products.

Using these assumptions and following Linnett's rules, several structures for  $\text{O}_3\text{F}_2$  can be postulated. The classical model of three catenated oxygens terminated by two fluorines (Figure 3a) is not satisfactory since a formal charge of +1 exists on the middle oxygen. If other structures are drawn using this same nuclear distribution, they can be rejected because of excessive charge on the oxygen nuclei and because the fluorine nuclei are nonequivalent. However, the principal reason for rejecting this model (and others involving catenated oxygen atoms) is that there is no simple way to get only  $\text{O}_2\text{F}_2$  and  $\text{O}_2$  as decomposition products.

Another possible structure involves a cyclic configuration of three oxygen atoms with fluorine attached to two of them (Figure 3b). This model can readily release oxygen forming  $\text{O}_2\text{F}_2$  as a decomposition product; however, the two " $\text{O}_2\text{F}_2$ " oxygens each have a formal charge of +1, and the "out-of-line" oxygen has a charge of -1. On the basis of charge distribution, this model is rejected.

A third structure in which  $\text{O}_3\text{F}_2$  is described as a dimer (Figure 3c) can be postulated. This structure suffers the same shortcomings as the monomer (Figure

(12) A. G. Streng, *Chem. Rev.*, **63**, 607 (1963).

Figure 3. Linnett structures for "O<sub>3</sub>F<sub>2</sub>" assuming its existence as a molecular entity.

3b) in that excessive formal charge is placed upon the oxygen nuclei.

Thus one is drawn to the conclusion based upon structural considerations and upon electronic distribution considerations that O<sub>3</sub>F<sub>2</sub> does not exist as discreet molecular units. This conclusion supports that drawn by Solomon and co-workers<sup>3</sup> on their nmr studies and is consistent with the observation of Malone and McGee<sup>13</sup> that the mass spectral cracking pattern of O<sub>3</sub>F<sub>2</sub> does not arise from a single molecular species.

What then is the nature of material with composition O<sub>3</sub>F<sub>2</sub>? Two possibilities exist. The first possibility is that O<sub>3</sub>F<sub>2</sub> is a 1:1 mixture of O<sub>2</sub>F<sub>2</sub> and O<sub>4</sub>F<sub>2</sub>. The structure of O<sub>4</sub>F<sub>2</sub> has recently been postulated as (OOF)<sub>n</sub>,<sup>14</sup> indicating that this compound is a polymer of the radical OOF. Linnett structures for the OOF radical can readily be drawn and are presented in Figure 4. In this case, "one-electron" bonds are favored over the normal fluorine-oxygen covalent bonds. The appearance of only one signal for "O<sub>3</sub>F<sub>2</sub>" suggests that the model of discreet O<sub>2</sub>F<sub>2</sub> and OOF species from O<sub>4</sub>F<sub>2</sub> is not correct. If it were, then two <sup>19</sup>F signals should be observed, one for each fluorine in the two species.

The second possibility, and the one which is preferred by the authors, is a model of O<sub>3</sub>F<sub>2</sub> containing "interstitial" oxygen molecules. This "interstitial" oxygen is held in the O<sub>2</sub>F<sub>2</sub> by forces too strong for it to be considered dissolved, but too weak for it to be considered bonded, even with "one-electron" bonds. However, the oxygen is bound strongly enough to alter significantly the <sup>19</sup>F nmr shift for O<sub>2</sub>F<sub>2</sub>.

This model is consistent with several observations on the system. First, although repeated analyses yielded an average stoichiometry of O<sub>3.0</sub>F<sub>2</sub>, individual analyses

Figure 4. Linnett structures for OOF radical.

ranged from O<sub>2.9</sub>F<sub>2</sub> to O<sub>3.1</sub>F<sub>2</sub>. Although small amounts of O<sub>2</sub>F<sub>2</sub> and O<sub>4</sub>F<sub>2</sub> can be formed during the preparation of O<sub>3</sub>F<sub>2</sub>, procedures were developed to remove both impurities prior to sampling. In addition, a much wider stoichiometric range (O<sub>2.5</sub>F<sub>2</sub> to O<sub>3.5</sub>F<sub>2</sub>) is found in the analyses if O<sub>4</sub>F<sub>2</sub> and O<sub>2</sub>F<sub>2</sub> are intentionally prepared with O<sub>3</sub>F<sub>2</sub>. Secondly, the recorded behavior of O<sub>3</sub>F<sub>2</sub> with temperature is indicative of unusual bonding. At 77°K, O<sub>3</sub>F<sub>2</sub> is a dark brownish red solid; at 83–84°K, the material melts to a dark red liquid; in the temperature interval 85 to 105°K (where O<sub>3</sub>F<sub>2</sub> is said to decompose<sup>4</sup>), the color becomes orange-red and nucleation of O<sub>2</sub>F<sub>2</sub> (yellow crystals) can be seen on the sides of sample tubes. The decomposition of the red liquid proceeds rapidly at 109°K and above. The color changes are accompanied by changes in the chemical shift of O<sub>3</sub>F<sub>2</sub>. However, temperature was found to have little effect on the chemical shift of pure O<sub>2</sub>F<sub>2</sub>. The shift of pure O<sub>2</sub>F<sub>2</sub> varied only about 2 ppm in the range of 110–145°K. Third, the only decomposition products of O<sub>3</sub>F<sub>2</sub> are O<sub>2</sub>F<sub>2</sub> and O<sub>2</sub>. There is no evidence of other decomposition products such as F<sub>2</sub> or OF<sub>2</sub>. Finally, epr spectra of samples of O<sub>3</sub>F<sub>2</sub> at 77°K showed the same anisotropic pattern present in spectra of O<sub>2</sub>F<sub>2</sub> samples at temperatures below 116°K. O<sub>2</sub>F<sub>2</sub> is said to melt at 84°K and to decompose quantitatively at 115°K.<sup>15</sup> Epr spectra of O<sub>3</sub>F<sub>2</sub> at temperatures between 88 and 115°K do not show the isotropic doublet expected from ·O<sub>2</sub>F in liquid O<sub>3</sub>F<sub>2</sub>, but rather the same anisotropic pattern observed in the spectrum of ·O<sub>2</sub>F in solid O<sub>2</sub>F<sub>2</sub>; a doublet is observed at temperatures above 110°K, the melting point of O<sub>2</sub>F<sub>2</sub>. From the behavior of the color changes described above and from the epr observations, it is concluded that samples of O<sub>3</sub>F<sub>2</sub> contain significant amounts of O<sub>2</sub>F<sub>2</sub>, and it is the epr spectrum of ·O<sub>2</sub>F in the latter compound which is observed from 88 to 115°K.<sup>16</sup>

The conclusions which we have reached are somewhat different from those reported by Solomon, *et al.*<sup>3</sup> These authors reported two incompletely resolved signals, whereas we observed only one broad signal which became more narrow with increasing temperature. Because of their observation of two <sup>19</sup>F nmr signals, Solomon, *et al.*, concluded that the two signals were due to O<sub>2</sub>F<sub>2</sub> and (OOF)<sub>n</sub>. However, we observed no significant shift of the <sup>19</sup>F nmr signal from pure O<sub>2</sub>F<sub>2</sub> in the range of 110 to 145°K. Solomon, *et al.*, report a considerable shift (–1900 ppm at 85°K) in both signals which they report. It is the opinion of the authors of this paper that if the Solomon model of O<sub>3</sub>F<sub>2</sub> as a mixture of O<sub>2</sub>F<sub>2</sub> and (OOF)<sub>n</sub> is correct, the

$O_2F_2$  signal should remain in its usual region while the (OOF) $_n$  signal would migrate with temperature until it coalesces with that of  $O_2F_2$ . Our results would indicate, and we believe that the temperature studies of Solomon, *et al.*, indicate also, that " $O_3F_2$ " cannot be as simply described as a mixture of  $O_2F_2$  and (OOF) $_n$ .

The ease with which  $O_3F_2$  reverts to  $O_2F_2$ , together with the fact that no really adequate structure can be drawn for  $O_3F_2$ , suggests a model of " $O_3F_2$ " in which "interstitial" oxygen is being held by  $O_2F_2$  molecules. Such a model fits the observations most fully. This model is further substantiated by mass spectral studies<sup>13</sup> which show that " $O_3F_2$ " can be described as  $O_2F_2$  plus  $O_2$ .

If one extends the model one step further and considers a 1:1 ratio of  $O_3F_2$  and  $O_2$ , it becomes apparent that the most reasonable structure in this instance is

(OOF) $_n$ , or the model for  $O_4F_2$  as suggested by infrared studies.<sup>14</sup>

An unequivocal interpretation of the  $^{19}F$  nmr signal from  $O_3F_2$  cannot be made at this time. It would appear that the key lies in the determination of  $^{19}F$  nmr shifts in the  $O_4F_2$  or in the OOF species. Our attempts to determine chemical shifts for  $O_4F_2$  were not successful, since the instability of this species is very much greater than that associated with  $O_2F_2$  or even " $O_3F_2$ ." With the development of more refined low-temperature nmr techniques, however, such information should be made available.

## On the Crystal Structure of Trimethylaluminum

R. G. Vranka<sup>1</sup> and E. L. Amma<sup>2</sup>

*Contribution from the Department of Chemistry, University of South Carolina, Columbia, South Carolina 29208. Received October 3, 1966*

**Abstract:** The crystal structure of trimethylaluminum has been redetermined by three-dimensional, single-crystal X-ray diffraction techniques from photographic data obtained at  $-50^\circ$ . Hydrogen as well as aluminum and carbon atoms were located. The structure consists of  $Al_2(CH_3)_6$  molecules with symmetrical Al-C-Al bridges. An Al-C-Al bridge angle of  $74.7 \pm 0.4^\circ$  and an Al-C bridge distance of  $2.14 \pm 0.01$  Å were found. The nonbridged Al-C distance is  $1.97 \pm 0.01$  Å. An Al-Al distance of  $2.600 \pm 0.004$  Å was found,  $\sim 0.1$  Å longer than previous results indicated. A significant molecular distortion involving the terminal carbon atoms makes the nuclear framework (excluding hydrogen) belong to point group  $C_{2h}$  instead of the idealized  $D_{3h}$ . There exists no experimental evidence to indicate that the bridge is not correctly described with a carbon  $sp_3$  orbital participating in a four-center, four-electron, electron-deficient bridge bond.

The original example of electron-deficient methyl bridge bonding was tetramethylplatinum,<sup>3</sup> which is now generally recognized as nonexistent.<sup>4</sup> Trimethylgallium has been shown to be monomeric down to very low temperatures<sup>5</sup> in benzene solution and in the pure liquid at room temperature.<sup>6</sup> Trimethylindium<sup>7,8</sup> is, at best, only very weakly bonded into a higher polymer. Hence, there exist at this time only three examples of "five-coordinate carbon" or electron-deficient methyl bridge bonds: dimethylberyllium,<sup>9</sup> dimethylmagnesium<sup>10</sup> (powder data only), and trimethylaluminum.<sup>11</sup> Previously, Amma<sup>12</sup> had attempted a refinement of the three-dimensional data of trimethylaluminum collected

in the original two-dimensional structure determination,<sup>11</sup> but the refinement failed to converge properly. Similar results have been obtained for the refinement of the photographic data of dimethylberyllium.<sup>13</sup> The failure of these refinements is probably due to the quality of the original diffraction data. With the availability of better vacuum-line<sup>14</sup> and low-temperature<sup>15</sup> techniques, we decided to reinvestigate this crystal structure because this compound is the prototype of methyl bridge electron-deficient bridging bonding and is important not only to the understanding of metal-alkyl bonds but also to the nature of intermediates in many organic reactions.

## Experimental Section

Trimethylaluminum was purchased from the Ethyl Corp. in a small cylinder, and a sample from this was removed into a storage tube in a vacuum line. The sample was sublimed several times and then sublimed directly into very thin-walled Pyrex capillaries.<sup>13</sup> The capillaries were then cut off under liquid nitrogen, and the melting point of the sample in each capillary was checked. Crystals were grown in a cold room at  $0^\circ$  and annealed with a small electric

H <sub>3C3</sub>	3.5	8kl	1.007	0.036

<sup>a</sup> The notation H<sub>1C1</sub> refers to H<sub>1</sub> on carbon atom C<sub>1</sub>. <sup>b</sup> Hydrogen coordinates and temperature factors not varied in least squares and no estimate of coordinate or temperature factor errors given. <sup>c</sup> The ratio of these scale factors was fixed by the isotropic refinement. The absolute value was fixed by the anisotropic refinement using one scale factor. However, the change in going from the isotropic to the anisotropic refinement was small.

light bulb. Crystals were checked for perfection in the cold room under a polarizing microscope and then transferred *via* a dewar to a Weissenberg camera completely enclosed in a double-walled Plexiglass housing,<sup>14</sup> cooled to  $-50^\circ$  by sublimation of Dry Ice.

**X-Ray Data.** The crystals were found to be monoclinic with unit cell constants determined by back-reflection techniques with Cu K $\alpha$  ( $\lambda = 1.5405$ ), K $\alpha_2$  ( $\lambda = 1.5443$ ):  $a = 12.74 \pm 0.02$  Å,  $b = 6.96 \pm 0.01$  Å,  $c = 14.63 \pm 0.02$  Å, and  $\beta = 123^\circ 40' \pm 15'$ . The observed systematic extinctions ( $hkl$ ,  $h + k = 2n + 1$ ;  $h0l$ ,  $h = 2n + 1$ ,  $l = 2n + 1$ ) limited the possible space groups to Cc or C2/c. The X-ray analysis indicated the correct space to be C2/c (*vide infra*). With eight molecules per unit cell the density was calculated as  $0.887 \text{ g cm}^{-3}$ , in favorable agreement with the density of liquid trimethylaluminum of  $0.752 \text{ g cm}^{-3}$ . Crystals used for the collection of intensity data were  $0.2 \times 0.2 \times 0.3$  mm or less in size. The linear absorption coefficient ( $\mu$ ) with Cu K $\alpha$  radiation is  $17 \text{ cm}^{-1}$  and with crystals of the size indicated above,  $\mu r$  is sufficiently small that absorption corrections could be neglected.

It was found that crystals could be grown with any of the three crystallographic directions parallel to the capillary axis. Standard equi-inclination multiple-film intensity data were obtained using nickel-filtered Cu K $\alpha$  radiation with the [100] and [010] directions as rotation axis. These data were visually estimated, correlated, and merged to yield 575 independent  $hkl$  intensities. The usual Lorentz polarization corrections were made.

## Structure Refinement

A three-dimensional Patterson and electron density function were computed to check the previous structure determination.<sup>16</sup> A least-squares refinement was carried out by minimizing the function  $\sum w(F_o - F_c)^2$  using

(16) Patterson and electron-density calculations made with the Sly-Shoemaker-van den Hende program, ERF-2.

the Busing and Levy program<sup>17</sup> on the IBM 7090. The Hughes<sup>18</sup> weighting scheme was used with  $4F_{\min} = 10.0$ . Scattering factors were from standard sources.<sup>19</sup> The variables for the isotropic refinement were the atomic coordinates, individual atom isotropic temperature factors for aluminum carbon, and the scale factors. The scale factors were allowed to vary at this stage, solely to check the accuracy of our data merging. As can be seen from Table I, the interlayer scaling is quite satisfactory. The anisotropic refinement had the atomic coordinates, six  $\beta_{ij}$  for each atom and one scale factor as variables.

Hydrogen atom positions were located from three-dimensional difference maps after the completion of the anisotropic refinement of the nonhydrogen atoms. These difference maps were computed with arbitrary  $\sin \theta$  cutoffs and inclusion of  $F(\text{calcd})$  terms for unobserved reflections. The best hydrogen atom resolution was obtained with a  $\sin \theta$  cutoff of 0.6. Attempts to refine the hydrogen positions by least squares were unsuccessful.

The shifts in atomic coordinates for the last least-squares cycle were less than  $5 \times 10^{-4}$  of a cell edge. The final disagreement index ( $R$ ),<sup>20</sup> the weighted  $R$ ,

and the standard error were found to be 0.117, 0.145, and 2.00, respectively. Without the hydrogen contribution, the disagreement index was 0.128. Attempts at refinement of the structure in the lower symmetry space group, Cc, led to large correlations ~0.9 for atoms that were symmetry related in C2/c. Refining one set while holding the other set fixed led to the centrosymmetric structure to within less than a standard deviation. Hence, the correct space group is the centric C2/c.

It is of considerable importance (*vide infra*) to ascertain if the bridging carbon (C<sub>1</sub>) can be equally well described as disordered along a line parallel to the Al-Al vector. We split C<sub>1</sub> into two carbon half-atoms and displaced them symmetrically about the C<sub>1</sub> position indicated in Table I. It was found that the atomic coordinates of these half-atoms were strongly correlated (>0.9) and could not be refined even with isotropic temperature factors. Attempts at refinement by fixing the coordinates of the carbon half-atoms and varying the coordinates of the other carbon half-atoms were equally unsuccessful. We conclude that within the limits of our experimental data the structure is best described by an ordered model with the thermal parameters indicated in Table III.

(20)  $R = \sum ||F_o| - |F_c|| / \sum |F_o|$ ; weighted  $R = \sum w||F_o| - |F_c|| / \sum w|F_o|$ ; standard error =  $[\sum (F_o - F_c)^2 / (NO - NV)]^{1/2}$  (NO = number of observations = 575; NV = number of variables = 37).

### Description of Structure

The crystal structure of trimethylaluminum consists of two monomers related by a center of symmetry to form a dimer with bridging methyl groups. These dimers are then separated by ordinary van der Waals' distances (Table II) to form a molecular crystal. Although these results are in general agreement with the features of the previous structure determination,<sup>11</sup> significant differences were found. In particular (1) the Al-Al distance is 2.600 ± 0.005 Å, ~0.1 Å longer; (2) the Al-C-Al angle is now 74.7 ± 0.4° compared to 70°; (3) the Al-C bridging distance is 2.14 ± 0.01 Å instead of 2.22 Å. However, our Al-C terminal distance is well within error of the earlier results. This terminal distance is in good agreement with the 2.00 Å observed in KF·2Al(C<sub>2</sub>H<sub>5</sub>)<sub>3</sub>,<sup>23</sup> and in (C<sub>6</sub>H<sub>5</sub>)<sub>3</sub>Al<sup>24</sup> as well as the 2.02 Å in LiAl(C<sub>2</sub>H<sub>5</sub>)<sub>4</sub>.<sup>25</sup> In the latter, some elongation is to be expected on chemical grounds. Our C<sub>1</sub>-Al-C<sub>2</sub> angle of 123.1° is to be compared with 112.1 and 108° in LiAl(C<sub>2</sub>H<sub>5</sub>)<sub>4</sub>. Although previously unreported, the short bridge methyl-carbon to terminal methyl-carbon distance of 3.3 Å is to be noted. The methyl-methyl nonbonded distances calculated from the sum of the van der Waals radii is 4.0 Å. All the intermolecular distances remain more or less normal, i.e., >3.9 Å (*cf.* Figures 1 and 2).

The most pronounced difference between our structure determination and earlier results is that we find a nonnegligible molecular distortion (Table II). The aluminum and terminal atoms of one dimer are not

(21) This tabulation and a more detailed form of this paper (or extended version, or material supplementary to this article) has been deposited as Document No. 9373 with the ADI Auxiliary Publications Project, Photoduplication Service, Library of Congress, Washington 25, D. Figure 1. Geometry, bond distances, and bond angles in the dimeric trimethylaluminum molecule. Methyl distances refer to carbon distances. Hydrogen atoms are not shown for reasons of simplicity.

coplanar. A separation of 0.12 Å is found between the parallel planes defined by  $\text{AlC}_2\text{C}_3$  and  $\text{Al}'\text{C}_1'\text{C}_3'$ . This distortion can also be seen from the angle of  $2.6 \pm 0.3^\circ$  between the  $\text{Al}-\text{Al}'$  line and the line defined as  $\text{Al}-(\text{bisector of } \text{C}_2-\text{C}_3)$ . Since the dihedral angle between the planes defined by  $\text{C}_2, \text{Al}, \text{C}_3$  and  $\text{C}_1', \text{Al}', \text{C}_3'$  is  $89.2 \pm 0.5^\circ$ , the molecular symmetry (exclusive of hydrogen) is  $\text{C}_{2h}$  with the twofold rotation axis bisecting the  $\text{Al}-\text{Al}'$  line and perpendicular to the  $\text{Al}-\text{C}_2-\text{Al}'\text{C}_1'$  plane. The origin of this distortion is not clear at this time.

Although we report hydrogen atom positions, the errors in these atomic coordinates are probably sufficiently large so that no physical significance should be attached to the differences in  $\text{C}-\text{H}$  bond distances and  $\text{H}-\text{C}-\text{H}$  bond angles.

#### Discussion

Since it is now clear that only the aluminum alkyls of the group III metal alkyls are dimerized with relatively strong  $\text{Al}-\text{C}-\text{Al}$  bridge bonds, the nature of this bridge is of particular importance. The aluminum alkyls have been extensively studied by infrared, Raman,<sup>26</sup> and nmr<sup>27</sup> spectroscopy, and it seems worthwhile at this point to relate our structure results to these other measurements.

The nmr spectrum of trimethylaluminum at room temperature consists of a sharp singlet in contrast to the two expected for the bridging and terminal groups. This indicates that the two species are either magnetically equivalent or are involved in a rapid exchange process.<sup>28</sup> At  $-75^\circ$  the spectrum<sup>27a</sup> consists of two resonances with an area ratio of 2:1, indicating a rapid exchange process at room temperature. At this time it is not possible to distinguish between two mechanisms for this exchange: (1) the breaking of one  $\text{Al}-\text{C}$  bridge bond which may re-form with a different methyl group

Figure 2. Perspective down the  $b$  axis indicating the arrangement of the dimeric molecules in the unit cell.

in the bridge and (2) a deformation of the molecule in which no bonds are broken, leading to an intermediate with four bridging methyl groups. These processes are shown in Scheme I.<sup>27b</sup>

Scheme I

Neither the nmr spectra, the infrared solution, nor vapor phase spectra down to  $300\text{ cm}^{-1}$  can distinguish between the symmetrically bridged structures I and IV ( $\text{D}_{2h}$  symmetry) or the asymmetric bridge ( $\text{C}_{2h}$  symmetry) structure V. This has led to speculation that

trimethylaluminum actually exists in dynamic equilibrium between the two asymmetrically bridged structures (VI). An equilibrium of this type would facilitate a bridge opening such as II and help to explain the rapid exchange process. Because of the limitations in the earlier diffraction data as well as the lack of computing facilities in that era of crystallography, neither structure V nor the dynamic equilibrium could be fully ruled out. The  $\text{Al}-\text{C}$  distances had an estimated standard

tion of  $\pm 0.02$  Å, but a more realistic appraisal have been  $\pm 0.04$ – $0.05$  Å.<sup>11</sup>

el that our structure determination rules out symmetric bridge features of structure V, but the  $C_{2h}$  symmetry of the dimer is, nevertheless,  $C_{2h}$  the fact that the aluminum and terminal carbon are not coplanar.

bridge distortion as in structure V was significant should manifest itself in one or more of the ways. One is a significant asymmetry in the Al–C–Al' bridge distances. This is not observed. The Al–C–Al' bridge is symmetric well within experimental error (Table III). Another is a statistical disordering of the molecules corresponding to two orientations related by a twofold rotation about an axis perpendicular to the Al–Al' line lying in the Al–C<sub>1</sub>–Al' plane. Hence, the bridging atoms could be ordered by two half carbon atoms symmetrically disordered along the Al–Al' direction. This model would require the C<sub>1</sub> and C<sub>2</sub> atoms to be disordered above and below a plane passing through Al and Al' perpendicular to the Al–C<sub>1</sub>–Al' bridge plane. There is no evidence for any disorder of the terminal carbon atoms. No satisfactory refinement could be achieved without data on a disordered bridging carbon half-occupied site (see above). Further, this model would require at least a pronounced C<sub>1</sub> thermal motion perpendicular to the Al–Al' line. This is not observed (Table II). Although we make no claims for accurate hydrogen positions, any disordering of carbons would make the location of hydrogen atoms impossible.

A dynamic equilibrium VI existed in the solid state; the disorder or thermal motion behavior described above should again be observed. These models have already been ruled out. Therefore, we conclude that trimethylaluminum does not exist as the dynamic equilibrium VI. The correct description of the geometry of trimethylaluminum is a dimer with symmetric bridge bonds and of point symmetry  $C_{2h}$  excluding hydrogen. The true over-all symmetry of the molecule would be  $\bar{1}$  (Ci).

proposed earlier by Rundle,<sup>11</sup> the bridge bonding in trimethylaluminum can be described either as a combination of tetrahedral orbitals from aluminum and carbon or as a "methylated double bond," the difference being mostly a matter of taste. In the former case, two bonding four-center MO's can be constructed from the carbon and aluminum tetrahedral orbitals of symmetry  $a_{1g}$  and  $b_{2g}$ , respectively (assuming  $C_{2h}$  symmetry). The four electrons (one from each aluminum and carbon) then completely fill these two molecular orbitals to give the closed-shell structure. The  $b_{2g}$  MO has a nodal plane through the aluminum and terminal carbon atoms and consequently this is a distorted  $\pi$  orbital.

With some overlap of the aluminum tetrahedral orbitals a metal–metal bent  $\sigma$  bond may be considered present as well. This formulation<sup>20</sup> bears a one-to-one correspondence to the description of diborane.<sup>20</sup>

Rundle<sup>11</sup> proposed that four principal factors govern the stability of dimers held together by alkyl bridges. Association is favored by (1) a large difference in electronegativity between the metal and carbon; (2) a low value for the energy required to promote an electron from an  $s$  to a  $p$  orbital in the valence shell of the metal; (3) a large bond energy for a normal single bond between the metal and carbon; (4) a minimal amount of inner shell repulsion between the two metal atoms separated by internuclear distances demanded by the geometry of the dimer. The first two make dimerization difficult for trimethylboron, and the last two probably act against formation of dimers by Ga, In, and Tl. If one examines the angles about Al, it is found that the C–Al–C<sub>2</sub> angle is  $123.1^\circ$ , the C–Al–Al' angle is  $118.7^\circ$ , and the C<sub>2</sub>–Al–Al' angle is  $118.2^\circ$ . These are strikingly close to the ideal  $120^\circ$  for  $sp^3$  hybridization. We would like to suggest, in addition to the above four factors (these are really not four independent variables), that overlap of metal–metal orbitals or metal–metal bonding is also important in the dimerization of the aluminum alkyls. Since the metal–metal bonding, in general, decreases in going down the periodic table (particularly after the 3rd row metals, e.g., Si, Ge, Sn, Pb), this also tends to destabilize the dimer for the group IIIb metal alkyls after aluminum.

If factor 1 above is important, then it is not clear why dimethylberyllium<sup>9</sup> and dimethylmagnesium<sup>10</sup> are polymeric with methyl bridges but dimethylzinc<sup>11</sup> is monomeric—particularly since Be and Zn have essentially the same electronegativity (1.5, 1.6)<sup>22a</sup> and the tetrahedral covalent radius of Zn (1.31) is less than that of Mg (1.40).<sup>22b</sup> However, when viewed in terms of metal–metal bonding, the fact that dimethylzinc is monomeric is not surprising. Alternatively, this trend is also understandable in terms of factor 3.

An examination of the tabulated  $s \rightarrow p$  excitation energies<sup>23</sup> shows that factor 2 cannot be the important factor for the lack of dimerization of trimethylboron. ( $B\ 2s \rightarrow 2p \sim 29,000\text{ cm}^{-1} \sim Al\ 3s \rightarrow 3p$ ). The most likely reason for the lack of dimerization of trimethylboron is probably a simple steric effect. An examination of the methyl–methyl nonbonding intramolecular distances in trimethylaluminum (Table II, Figure 1) shows that the methyl groups are already tightly packed and a substantial reduction in the size of the metal atom would create a good deal of van der Waals repulsion (covalent radii (Å): Al = 1.26, B = 0.88, but Be = 1.06). Therefore, with the additional data now available, factors 3 and 4 seem to be the most important. However, metal–metal bonding as well as steric repulsions are not to be neglected.

the earlier results,<sup>7</sup> but the estimates of error are probably more realistic. It is to be noted that In(CH<sub>3</sub>)<sub>3</sub> is still planar well within statistical error, and the "pseudo-tetramer" should be viewed as very weakly bonded together, if at all. Where weak chemical bonds begin and end is by no means a clear-cut, unambiguous decision.

## Steric Effects in Fast Metal Complex Substitution Reactions. II<sup>†</sup>

A. Kowalak,<sup>2a</sup> K. Kustin, R. F. Pasternack,<sup>2b</sup> and S. Petrucci<sup>2c</sup>

*Contribution from the Department of Chemistry, Brandeis University, Waltham, Massachusetts 02154. Received November 10, 1966*

**Abstract:** The rate constants for the formation and dissociation of nickel(II) and cobalt(II) complexes with  $\alpha$ - and  $\beta$ -aminobutyric acids have been determined by the temperature-jump method. Although rate constants for formation of higher order as well as monosubstituted complexes were measured, the most significant results with respect to a comparison between the two different metal ions concern the rate constants ( $k_1$ ) for the first substitution. It was determined that substitution for both nickel(II) and cobalt(II) is faster with  $\alpha$ -aminobutyric acid than with the  $\beta$  acid. That is, at  $20^\circ$  an ionic strength =  $0.1 M$  for nickel(II) with  $\alpha$ -aminobutyrate,  $k_1 = 1.0 \times 10^4 M^{-1} \text{ sec}^{-1}$ ; with  $\beta$ -aminobutyrate,  $k_1 = 4.0 \times 10^3 M^{-1} \text{ sec}^{-1}$ . Under the same conditions, for cobalt(II) with  $\alpha$ -aminobutyrate,  $k_1 = 2.5 \times 10^4 M^{-1} \text{ sec}^{-1}$ ; with  $\beta$ -aminobutyrate,  $k_1 = 2.0 \times 10^4 M^{-1} \text{ sec}^{-1}$ . The relative error for these rate constants is  $\pm 20\%$ . The rate constants determined for  $\alpha$ -aminobutyric acid are consistent with a mechanism in which release of a water molecule from the metal ion's inner coordination sphere is rate determining. In reaching this conclusion, it is shown that an empirical factor of  $1/3$ , to account for the partial absence of spherical symmetry in these chelating agents, must be used when comparing these (and the  $\beta$ ) values with rate constants previously determined for other ligands. The slower reactions with  $\beta$ -aminobutyric acid are explained by the kinetic chelate effect, in which chelate ring closure is the rate-determining step. The steric effect is appreciably greater for cobalt(II) than for nickel(II) because of the inherently greater lability of the former ion.

Studies of fast metal complex substitution reactions can be explained by a previously proposed mechanism for the formation of complexes between divalent ions and simple anionic ligands.<sup>2-4</sup> The initial process is the diffusion-controlled, ion-pair formation between the aquated metal ion and ligand. For most monodentate and certain polydentate ligands, the rate-determining step is the loss of a water molecule with concomitant substitution of the reactant ligand into the inner coordination shell. Since the rate-determining step is controlled by the rate of release of a water molecule from the inner coordination sphere, it is therefore a characteristic of the metal ion.

For metal complexes with multidentate ligands, the stability of the metal chelate is, in part, governed by the chelate structure.<sup>7</sup> The thermodynamic data for divalent metal ions with amino acids show that a five-membered ring is more stable, unless a linear complex is formed. For example, the stability constants for  $\alpha$ - and  $\beta$ -aminobutyric acids differ by over a factor of 10 (see Table I).

Recently, evidence has been reported that there is also a kinetic chelate effect.<sup>6</sup> Studies of divalent metal chelates with  $\alpha$ - and  $\beta$ -alanine show that there is a decrease in rate when changing the ligand from  $\alpha$ -alanine to  $\beta$ -alanine. This decrease in rate is explained by the difficulty in forming a six-membered, as opposed to a five-membered, ring with an aminocarboxylic acid ligand. The mechanism is the same as that originally proposed, but the rate-determining step is believed to be closing of the chelate ring rather than the release of a water molecule from the inner coordination sphere of the metal ion.

The kinetics for the formation of nickel(II) and cobalt(II) chelates with  $\alpha$ - and  $\beta$ -aminobutyric acid ( $\alpha$ -

$\alpha$  and  $\beta$ -Abu, respectively) have been examined to investigate further the possibility of a kinetic chelate effect. The stability constants for all the aminobutyric ligand-metal complex systems have not been previously reported. The stability constants that have been used were measured in this laboratory by a potentiometric method. The details for the determination of these constants will be published separately.<sup>8</sup> The results of the thermodynamic investigation, as well as other pertinent equilibrium constants, are given in Table I.

**Experimental Section**

Reagent grade  $KNO_3$ ,  $Ni(NO_3)_2 \cdot 6H_2O$ , and  $Co(NO_3)_2 \cdot 6H_2O$  were used without further purification, as were all other reagents. The  $\alpha$ -aminobutyric acid and  $\beta$ -aminobutyric acid were from Biochemical Co. products. Phenolphthalein (Baker reagent grade) and phenol red (Aldrich reagent grade) were used as indicators.

Stock solutions of the metal nitrate, acid ligand, and indicator were prepared. The solutions to be studied were made up by mixing the desired amounts of stock solutions into 100-ml volumetric flasks and diluting to the mark. The pH was adjusted by dropwise addition of solutions of NaOH and/or HNO<sub>3</sub>. The final pH value was measured by a pH meter (Radiometer, Copenhagen), within 0.01 pH unit.

The ionic strength of all solutions was 0.1 M. The temperature of the study was  $20 \pm 1^\circ$  for all experiments. The details of the temperature-jump instrumentation have been described elsewhere.<sup>9</sup>

K. Kustin and R. Davidow, submitted for publication. Cf. L. G. Martell and A. E. Martell, "Stability Constants of Metal-Ion Complexes," Chemical Society, London, 1964, Table 249, in which the first- and second-step stability constants for cobalt(II) and  $\alpha$ -aminobutyric acid are given as  $K_1 = 1.9 \times 10^4$ ,  $K_2 = 2.1 \times 10^3 M^{-1}$  at ionic strength 0.1 M and 30°.

Blank experiments with solutions containing only the metal and indicator, or the acid ligand and the indicator (both solutions at ionic strength 0.1 M), did not show any relaxation effect in the time range of the instrument.

**Results**

The relaxation times for the various solutions were computed and averaged from at least three (generally, five) photographs of the oscilloscopic traces. The averages of the relaxation times are reported in Tables II and III together with the pH and total concentrations of metal and ligand. The relaxation times thus evaluated have errors of  $\pm 20\%$  with respect to the reported averages. It should also be noted that the pH range of this study is from pH 8.0 to 9.2. The calculated relaxation times in Tables II and III were obtained (*vide infra*) by use of the best set of rate constants without the introduction of any pH-dependent terms.

A pH dependence of the rate constant would result from side reactions involving the neutral ligand, HL, or any hypothetical species  $MOH^+$ , where  $M = Ni^{2+}$  or  $Co^{2+}$ . The lack of a dependence of the rate constants on pH makes these steps insignificant under the conditions of this investigation. A more extensive variation of pH was precluded at the upper end by the precipitation of the metal (as metal hydroxide, presumably) and, at the lower end, by diminution of the amplitude of the relaxation effect. Indeed, by lowering the pH, the free  $L^-$  concentration decreases with respect

to the relatively inert HL, thus depriving the solution of reacting ligand.

The equilibrium concentrations for the species M, ML, ML<sub>2</sub>, ML<sub>3</sub>, L, HL, and H<sub>2</sub>L for the various solutions were calculated using the constants in Table I, with the help of a computer program run on an IBM 1620.

The relaxation processes observed were interpreted in terms of reactions of the type

where  $n = 1, 2$ , or  $3$ . The symbol L refers to the anionic form of the ligand, which is responsible for complexation of the metal ion. (Charges have been neglected in this and all other equations.) The general treatment given by Hammes and Steinfeld<sup>4</sup> for a system of two coupled reactions has been used in calculating the relaxation times. The relation

$$\tau^{-2} - \tau^{-1}(a_{11} + a_{22}) + (a_{11}a_{22} - a_{12}a_{21}) = 0 \quad (2)$$

derived from the solution of the secular determinant

$$\begin{vmatrix} a_{11} - 1/\tau & a_{12} \\ a_{21} & a_{22} - 1/\tau \end{vmatrix} = 0 \quad (3)$$

where  $1/\tau$  is the eigenvalue, was used to find the rate constants when two reactions of type 1 were present. In (3), the  $a_{ij}$ 's are related to (1) the concentrations of the appropriate reactants, (2) the rate constants, and (3) the equilibrium constants for the coupled fast (relative to the metal complexation) reactions

where the symbol In represents the indicator anion form.<sup>4</sup>

Calculation of  $\tau$  by trial-and-error methods employing appropriately varying values of the  $k_n$  for the two processes where  $n = 1$  and  $2$  were performed. In some cases the concentration of ML<sub>2</sub> was sufficiently high to enable the determination of all three rate constants, via solutions of (2) in which  $n = 2$  and  $3$ . The rate

constants used to calculate the relaxation times reported in Tables II and III are given in Table IV.

## Discussion

**General Mechanism.** The mechanism for metal chelate substitution reactions may be written as shown in eq a-c, where W<sub>1</sub> and W<sub>2</sub> represent the two water

molecules in the inner coordination sphere which are eventually replaced by the bidentate ligand. The two binding sites of the ligand are represented as A and B. Reaction a is the formation of the ion pair, W<sub>2</sub>MW<sub>1</sub>A-B with K<sub>a</sub> the ion-pair formation constant.

If we restrict our attention to the first substitution only, and use the assumptions made in part I,<sup>6</sup> we can relate the observed rate constants to the above mechanism by eq 4a and b. This mechanism shows two limit-

$$k_1 = k_0K_a \left( \frac{k_0'}{k_{-0} + k_0'} \right) \quad (4a)$$

$$k_{-1} = k_{-0} \left( \frac{k_{-0}'}{k_{-0} + k_{-0}'} \right) \quad (4b)$$

ing types of behavior, depending upon the relative magnitudes of the two rate constants  $k_{-0}$  and  $k_1'$ . These cases are summarized below as normal substitution,  $k_0' \gg k_{-0}$ ,  $k_1 = k_0K_a$  ( $M^{-1} \text{ sec}^{-1}$ ),  $k_{-1} = k_{-0}/K_c$  ( $\text{sec}^{-1}$ ); and sterically controlled substitution,  $k_{-0} \gg k_0'$ ,  $k_1 = k_0'K_aK_b$  ( $M^{-1} \text{ sec}^{-1}$ ),  $k_{-1} = k_{-0}'$  ( $\text{sec}^{-1}$ ).

If the complex formation is a "normal" substitution, then by using a calculated value for the ion-pair constant, K<sub>a</sub>, one obtains a value for  $k_0$ , the rate constant for the elimination of water from the first coordination sphere. Swift and Connick<sup>10</sup> have determined  $k_1$  by the use of nmr line-broadening measurements. Their values are  $3 \times 10^4$  and  $1 \times 10^6 \text{ sec}^{-1}$  for nickel-

(10) T. J. Swift and R. E. Connick, *J. Chem. Phys.*, **37**, 307 (1962); **41**, 2553 (1964).

nd cobalt(II), respectively. The results for glycine and  $\alpha$ -alanine<sup>6</sup> are in good agreement with the  $\gamma_{\pm}$  values. The results for  $k_1 (=k_0K_a)$  reported for  $\text{Ni}^{2+}$  and  $\text{Co}^{2+}$  with  $\alpha$ -aminobutyric acid are  $10^4$  and  $2.5 \times 10^6 \text{ M}^{-1} \text{ sec}^{-1}$ , respectively, which agree qualitatively with the nmr data, and with data obtained with other ligands.

more evidence on the nature of metal complex substitution reactions accumulates, resort is being made to investigations with increasingly larger and more complex ligands. It would be worthwhile to reexamine the applicability of ion-pair formation constant relations in this regard. The constant for ion-pair formation between two ions leading to a solvated species L can be calculated with the function derived independently by Fuoss<sup>11</sup> on statistical and by Eigen<sup>12</sup> on c grounds, namely

$$K_a = \frac{4\pi N a^3}{3000} \exp(b) \exp[-b\kappa a/(1 + \kappa a)] \text{ M}^{-1} \quad (5)$$

In the above expression,  $N$  is Avogadro's number;  $[-b\kappa a/(1 + \kappa a)] = \gamma_{\pm}^2$ , which is the square of the Debye-Hückel mean activity coefficient;  $a$  is the minimum approach distance between the charged particles; the Bjerrum ratio between potential and kinetic energy ( $b = |Z_M Z_L| e_0^2 / a D k T$ ) where  $Z_M$  and  $Z_L$  are the charges,  $e_0$  is the elementary charge,  $k$  is the Boltzmann constant,  $D$  is the dielectric constant, and  $T$  is the absolute temperature; the parameter  $\kappa$  is the reciprocal of the Debye length (the distance between the central ion and the ionic sphere at the maximum of its charge density according to the Debye-Hückel theory).

Equation 5 has been based on models in which the solvent is assumed to be a continuum and the ions are considered to be rigid spheres of radii  $a/2$ . It is evident that for the anions discussed in this study this model does not fit, even to a first approximation, the molecular structures of these amino acids. The extension is, moreover, strongly dependent on the distance  $a$ . Choosing  $a = 5 \text{ \AA}$ , as has been done,<sup>4</sup> leads to a value of  $K_a = 2 \text{ M}^{-1}$ . While this procedure yields reasonable results, in some cases, we feel that to expect agreement with the theory for ligands of different complexity is impractical. On the other hand, attempts to adapt the model—and, hence, the theory—to the present situation, would involve efforts out of keeping with a kinetic study. We are mainly interested in a direct comparison of the observed  $k_1$  between  $\alpha$ -aminobutyric acid complexes with cobalt(II) and nickel(II). Therefore, even if the absolute value of  $K_a$  is unknown, some of its characteristics with respect to the two ligands may be inferred, and we may draw valid conclusions about the mechanism.

The  $k_1$  value for nickel with  $\alpha$ -aminobutyric acid is what lower than the corresponding value for other ligands (e.g., glycine,  $\alpha$ -alanine, diglycine). And, the same is true for the cobalt values, and, as will later be shown, the rate constants for  $\beta$ -aminobutyric acid, as well. To find the reason for this decrease, we start by examining eq 5. This expression consists of two parts. The preexponential factor is of ionic nature. It increases with increasing ionic strength, reflecting the enhanced probability of pairing

as the reaction cross section increases. The exponential factor is the energy part and is controlled mainly by the electrostatic interaction. This factor decreases with increasing ionic size. Calculations indicate that, at this temperature and ionic strength, the function is at this minimum point, being almost insensitive to size for  $3 < a < 8 \text{ (\AA)}$ . Moreover, the electrostatic (exponential) term begins to show inappreciable change with ionic size as  $a$  increases beyond 5 or 6  $\text{\AA}$ . It would thus appear that, in this range, larger ligand size makes the electrostatic interactions less significant, while increasing  $K_a$ , which would also increase the observed rate constants, rather than decrease them.

However, an increase in ligand size has been achieved in this case at the expense of spherical symmetry. This effect would be directly manifested in the rate constant for formation of the ion pair (as shown by Eigen, *et al.*,<sup>13</sup>), thereby reducing  $K_a$  in magnitude. Essentially then, we assume that the important effect on  $K_a$  is given by the diminished accessibility of ion-pairing sites on the ligand. To adjust for this reduction in the solid angle corresponding to reactive encounters, we shall introduce an empirical factor of approximately  $1/2$  into eq 5.<sup>14</sup> The basis for introducing this factor will be explained more fully as we discuss each ion in detail.

**Nickel(II).** The observed value of  $k_1$  for  $\text{Ni}^{2+}$  and  $\alpha$ -aminobutyrate is  $1.0 \times 10^4 \text{ M}^{-1} \text{ sec}^{-1}$ . The value for  $\alpha$ -alanine, also determined in this laboratory, is  $2.0 \times 10^4 \text{ M}^{-1} \text{ sec}^{-1}$ , from which the previously discussed empirical factor of  $1/2$  has been obtained by taking the ratio of these rate constants. The increased rates of formation of the higher order complexes is explained by a loosening in the binding between the metal ion and the remaining coordinated waters.<sup>4</sup> The results for the  $\alpha$ -aminobutyric acid, in comparison to  $\alpha$ -alanine, lead to the conclusion that the mechanism of substitution is "normal"; that is, the rate-determining step is given by reaction b.

The value of  $k_1$  for  $\text{Ni}^{2+}$  and  $\beta$ -aminobutyrate is less than that reported for the  $\alpha$  complex, *viz.*,  $4 \times 10^3 \text{ M}^{-1} \text{ sec}^{-1}$  as compared to  $1 \times 10^4 \text{ M}^{-1} \text{ sec}^{-1}$ . This difference is most interesting when one considers that a similar result was observed for  $\alpha$ - and  $\beta$ -alanine, the value of the latter being one-half as large as the  $\alpha$ -Ala  $k_1$  (where Ala = alanine). If the reduction in the  $\beta$ -aminobutyric acid rate constant is assumed to indicate partial steric control, then one-half the  $k_1$  for  $\alpha$ -aminobutyric acid (where  $1/2 = k_1(\beta\text{-Ala})/k_1(\alpha\text{-Ala})$ ), or  $5 \times 10^3 \text{ M}^{-1} \text{ sec}^{-1}$ , should be the approximate value for  $k_1$  when  $\beta$ -aminobutyric acid is the ligand. The measured value of  $4 \times 10^3 \text{ M}^{-1} \text{ sec}^{-1}$  is in good agreement with this hypothesis.

**Cobalt(II).** The rate constants for formation of the first and second  $\alpha$  complexes, as given in Table IV, are  $k_1 = 2.5 \times 10^6$  and  $k_2 = 1.9 \times 10^6 \text{ M}^{-1} \text{ sec}^{-1}$ , while  $k_3$  could not be determined. The fact that  $k_2$  is larger than  $k_1$  corresponds to the loosening of the waters in the first coordination sphere, as in the nickel case. This effect is larger than for nickel(II), however, and may reflect the greater crystal-field stabilization of a  $d^8$  ion. As noted before, the value of  $k_1$  is somewhat less

than anticipated for normal substitution. The empirical factor can be calculated from the ratio of rate constants as  $k_1(\alpha\text{-Abu})/k_1(\alpha\text{-Ala}) = 2.5/6 = 0.42$  and  $k_1(\alpha\text{-Abu})/k_1(\text{Gly}) = 0.54$  (Gly = glycine). The average value is, again, approximately  $1/2$ . This result compares favorably with the procedure adopted for the  $\text{Ni}^{2+}$  complexes. Thus, this relatively small difference in the value of  $k_1$  can be explained, and the substitution classified as normal.

For  $\beta$ -aminobutyric acid, values of  $k_1 = 2 \times 10^4$  and  $k_2 = 7 \times 10^4 \text{ M}^{-1} \text{ sec}^{-1}$  were found. Although  $k_2$  is larger than  $k_1$ , the effect is not nearly as pronounced as for  $\alpha$ -aminobutyric acid. Moreover, the value of  $k_1$  is significantly lower than the corresponding value for  $\alpha$ -aminobutyric acid or glycine, being reduced, primarily, by the factor  $(1 + k_{-0}/k_0')^{-1}$ . Here, a steric effect due to the difficulty of closing the six-membered ring in the chelate complex can be postulated, as in the case of  $\beta$ -alanine,<sup>6</sup> where it was also indicated that the

limiting case ( $k_{-0} \gg k_0'$ ) was not reached. It is thus possible to predict the value of  $k_1$  for the  $\beta$  complex by a semiempirical calculation as follows.

Let us assume that the steric effect appearing in  $\text{Co}^{2+}$ - $\beta$ -alanine reactions is roughly equal to the steric effect with  $\beta$ -aminobutyric acid. Then the rate constant for  $\text{Co}^{2+} + \beta$ -aminobutyrate is  $k_1(\beta\text{-Abu}) = k_1(\alpha\text{-Abu}) \cdot [k_1(\beta\text{-Ala})/k_1(\alpha\text{-Ala})] = 2.5 \times 10^4 (7.5/60) = 3.1 \times 10^4 \text{ M}^{-1} \text{ sec}^{-1}$ . The same calculation can be performed in an alternate way. Suppose that the ratio (7.5/60) expresses the steric control contribution to the closing of the six-membered ring with respect to the five-membered ring. Then, the  $\beta$  rate constant can be calculated from  $k_1(\text{Gly})$  by the introduction of the statistical collision factor  $P = 1/2$ , to adjust for the decreased active "surface of reaction." Therefore,  $k_1(\beta\text{-Abu}) = Pk_1(\text{Gly})[k_1(\beta\text{-Ala})/k_1(\alpha\text{-Ala})] = 1/2(4.6 \times 10^4)(7.5/60) = 2.9 \times 10^4 \text{ M}^{-1} \text{ sec}^{-1}$ , while the experimental value is  $k_1 = 2.0 \times 10^4 \text{ M}^{-1} \text{ sec}^{-1}$ .

## Nucleophilic Reactivity in Substitution Reactions of Square-Planar Metal Complexes. II. A Comparison of the Kinetic Behavior of Platinum(II) and Gold(III) Complexes

L. Cattalini, A. Orio, and M. L. Tobe

*Contribution from Istituto di Chimica Generale, Centro Composti di Coordinazione del C. N. R., Padua, Italy, and the William Ramsay and Ralph Forster Laboratories, University College, London W.C.1., England. Received January 16, 1967*

**Abstract:** The kinetics of the displacement of chloride from the  $[\text{AuCl}_4]^-$  anion by pyridine,  $\text{NO}_2^-$ ,  $\text{N}_3^-$ ,  $\text{Br}^-$ ,  $\text{I}^-$ , and  $\text{SCN}^-$  in methanol have been studied over a range of temperature and reagent concentration. The usual two-term rate law is observed, and the rate constants and Arrhenius parameters are reported and compared with the data for the analogous  $[\text{PtCl}_4]^{2-}$  anion. The discriminating power of the Au(III) reaction center is found to be very much greater than that of Pt(II) in a similar ligand environment, and an explanation is offered in terms of the extent to which the mechanism moves from an associative toward a synchronous bimolecular process.

Although kinetic studies of nucleophilic displacement of ligands from square complexes of  $d^8$  transition metal ions have, in the past, been limited mainly to those of platinum(II),<sup>1</sup> sufficient information about the behavior of corresponding gold(III) complexes has now become available for it to be possible to attempt to make a preliminary general comparison of the kinetic behavior of Pt(II) and Au(III) substrates.

In part I,<sup>2</sup> the factors which determine the reactivity of nucleophiles toward Pt(II) complexes were discussed. It was shown that, apart from biphilic reagents, such as  $\text{NO}_2^-$ ,  $\text{SeCN}^-$  and thiourea, the sequence of relative reactivity followed a linear free-energy relationship with the index,  $n_{\text{Pt}}$ ,<sup>3</sup> defined by  $n_{\text{Pt}} = \log(k_2/k_s)$ , where  $k_2$  and  $k_s$  are the second-order rate constant for the entry of the nucleophile in question and the

first-order rate constant for the solvolysis by methanol, respectively, of the reference substrate *trans*- $[\text{Pt}(\text{py})_2\text{Cl}_2]$ . This was taken to be a measure of the "softness" or micropolarizability of the entering nucleophile since its basicity appeared to have only a minor effect upon its reactivity.

In order to make the comparison between Pt(II) and Au(III) complexes, it was necessary to augment the available data relative to nucleophilic displacement reactions of the gold(III) derivatives. Apart from the isotopic exchange<sup>4</sup> of chloride ion with  $[\text{AuCl}_4]^-$  and from the reactions<sup>5</sup> of some nucleophiles on the cationic complex  $[\text{Au}(\text{dien-H})\text{Cl}]^+$ , the processes studied until now were mainly limited to the use of pyridine derivatives, either as entering<sup>6,7</sup> or leaving<sup>8,9</sup> groups. We have therefore studied the reactions of  $[\text{AuCl}_4]^-$  with

ine and with the anionic nucleophiles  $\text{NO}_2^-$ ,  $\text{Br}^-$ ,  $\text{I}^-$ , and  $\text{SCN}^-$  in methanol. This has not provided a new set of data and a sequence of nucleophilicity toward an anionic Au(III) substrate, but it also made it possible to make a direct comparison of the behavior of the isoelectronic and isosubstituted  $[\text{AuCl}_4]^-$  and  $[\text{PtCl}_4]^{2-}$ . This second point is important, since the kinetic behavior of both Au(III) and Au(II) substrates appears to depend as much upon the nature of the ligands coordinated to metal as it does upon the total charge of the complex. For example, it has been shown<sup>2</sup> that, in Pt(II) complexes, the nucleophilic discrimination factor,<sup>8</sup>  $s$ , by eq 1, changes from 0.8 to 1.6 in a series of

$$\log k_2 = s(n_{\text{Pt}}) + \log k_1 \quad (1)$$

for Pt(II) complexes, whereas it is 0.312 for  $[\text{PtCl}_4]^{2-}$ . Similarly, the Brønsted coefficient,  $\alpha$ , in eq 2, which

$$\log k_2 = \alpha(pK_a) + \text{constant} \quad (2)$$

relates the basicity of the substituted pyridine with the free energy of activation of their reaction with gold(III) substrates, changes from 0.21 to 0.89 in a series of monocationic complex cations,<sup>7</sup> whereas 0.15 for  $[\text{AuCl}_4]^-$  as substrate.

## Experimental Section

**Materials.** Chloroauric acid was recrystallized and its purity checked by analysis and comparison of its ultraviolet spectrum with published values.<sup>10,11</sup> The other chemicals used were all all reagent grade materials. The methanol was dried by refluxing over  $\text{Mg}(\text{CH}_3\text{O})_2$ , and the distilled product was stored under anhydrous conditions. There was no indication that rigorous purification of the materials was necessary in order to obtain reproducibility.<sup>12</sup>

**Procedures.** The reactions were studied spectrophotometrically by the procedure described in part I<sup>1</sup> in which the changes of optical density at a selected wavelength in the ultraviolet region were followed over a period of time by means of an Optical-CF4 double-recording spectrophotometer, with the appropriate attachment to maintain the cells at constant temperature ( $\pm 0.1^\circ$ ). The reactions were started by mixing known volumes of standard solutions of the reagents in the spectrophotometer cell which also served as the reaction vessel. Constant ionic strength was maintained by the addition of lithium perchlorate solution. Freshly prepared solutions of  $\text{HAuCl}_4$  were used for each experiment in order to avoid the formation of significant quantities of the solvento complexes. The entering reagent was always present in sufficient excess to provide pseudo-first-order conditions and to avoid complications from the reverse reactions. The pseudo-first-order rate constants,  $k_{\text{obsd}}$ , were calculated from the slope of the plot of  $\log(D_\infty - D_t)$  against time, where  $D_t$  and  $D_\infty$  are the optical densities of the reaction mixture at time  $t$  and at the end of the reaction, respectively.

its

The problems of following the kinetics of nucleophilic ligand displacements from  $[\text{AuCl}_4]^-$  are, in principle, similar to those encountered in the study of the reactions of  $[\text{PtCl}_4]^{2-}$  since, in both the substrates, there are four replaceable groups. However, the lower reactivity of the gold(III) substrate and the possibility of complication by redox processes can add extra difficulty. Owing to the relatively high reactivity of  $[\text{AuCl}_4]^-$ , we have had to limit our study to nucleophiles pyridine,  $\text{NO}_2^-$ ,  $\text{N}_3^-$ ,  $\text{Br}^-$ ,  $\text{I}^-$ ,

$\text{SCN}^-$ , and  $\text{CH}_3\text{OH}$ . Fortunately, as was previously reported for the nucleophilic substitutions of neutral complexes of the type  $[\text{AuCl}_3\text{am}]$ ,<sup>8</sup> the reduction of Au(III) to Au(I), or even to metallic gold, either did not occur or else was relatively slow in comparison to the ligand displacement reaction. No evidence was found for any irreproducible redox-catalyzed substitution of the type observed by Rich and Taube<sup>12</sup> in their studies of the chloride exchange.

All the reaction rates reported in this paper are concerned with the replacement of the first of the four chloride ligands bonded to the gold. As far as the reagents  $\text{NO}_2^-$ ,  $\text{N}_3^-$ , and  $\text{Br}^-$  are concerned, the identification of the reaction steps and the products is based upon the same arguments that were previously used for the reactions of  $[\text{AuCl}_3\text{am}]$ .<sup>8</sup> In each case, two reaction steps can be observed, and the isosbestic points for the second step occur at least at one wavelength where there is a large enough change in optical density corresponding to the first step. These isosbestic points are identical with those observed in the appropriate stages of the analogous reactions with the  $[\text{AuCl}_3\text{am}]$  substrate,<sup>8,9</sup> and the kinetics of the first stage were studied at these wavelengths. In these cases it is also found that the general kinetic behavior, after the first stage of the reaction, also corresponds to that observed for the substrates of the type  $[\text{AuCl}_3\text{am}]$ , and the final spectra are also in agreement with those previously observed. Consequently, the reactions can be described as

The rates of the second reaction step are not reported here.

The reactions with  $\text{NO}_2^-$  were carried out in the presence of a small quantity of  $\text{CH}_3\text{O}^-$  in order to avoid the formation of  $\text{HNO}_2$ . Some preliminary experiments showed that this species can exert a catalytic effect similar to that observed for the reactions of some platinum(II) complexes.<sup>13</sup> It should be pointed out that a similar effect was not observed in the reactions of  $[\text{AuCl}_3\text{am}]$ , and further studies of this phenomenon are now in progress.

With pyridine and methanol as entering groups, the reaction appears to stop when only one chloride is replaced. The reaction with pyridine at  $25^\circ$  has been reported previously.<sup>6</sup> The rate constant for the reaction with the solvent methanol is the  $k_1$  value from the two-term rate law.

The reactions with  $\text{I}^-$  and  $\text{SCN}^-$  appear to occur in a single stage. The initial spectrum corresponds to that of the  $[\text{AuCl}_4]^-$  starting material, and so the rate-determining step is the replacement of the first chloride. The final spectrum for the reaction with  $\text{I}^-$  corresponds exactly to that of  $[\text{AuI}_4]^-$ .<sup>10</sup> An attempt was made to follow the reaction with thiourea at  $6^\circ$ . The reaction

was very fast, even at low concentrations of this reagent, and it is possible only to say that the second-order rate constant  $k_2$  is approximately 400 l. mole<sup>-1</sup> sec<sup>-1</sup>.

The pseudo-first-order rate constants ( $k_{\text{obsd}}$ ) obtained in these studies are listed in Table I. All the reactions follow the usual two-term rate law, *viz.*, rate =  $(k_1 + k_2[Y])[\text{complex}]$ , where Y is the entering nucleophile. The values of  $k_1$  and  $k_2$  were obtained as the intercepts and slopes, respectively, of linear plots of  $k_{\text{obsd}}$  against [Y]. The values of  $k_1$  and  $k_2$  are collected in Table II together with the derived activation parameters.

## Discussion

On comparing the rate constants for the entry of the various nucleophiles into the  $[\text{AuCl}_4]^-$  anion with those for the analogous reactions of  $[\text{PtCl}_4]^{2-}$ , which are also given in Table II, it is apparent that, in all cases, the Au(III) complex reacts considerably faster than does that of Pt(II).<sup>14</sup> This cannot be explained simply by

(14) The data for  $[\text{PtCl}_4]^{2-}$  in Table II have been corrected for ionic strength effects and therefore refer to a standard state of pure water. No attempt has been made to treat the data for  $[\text{AuCl}_4]^-$  in a similar fashion because of the unreliability of an extrapolation from an ionic strength of 0.1 when methanol (with its smaller dielectric constant) is

; that the Pt(II) data refer to aqueous solution or the lower charge of the  $[\text{AuCl}_4]^-$  anion causes less electrostatic repulsion between the approaching reagent because this observation is more general. For example, the exchange of isotopically labeled chloride  $[\text{AuCl}_4]^-$  has a  $k_2$  value of  $0.147 \text{ M}^{-1} \text{ sec}^{-1}$  in water<sup>3,4</sup> whereas with  $[\text{PtCl}_4]^{2-}$  the bimolecular exchange of chloride is not experimentally detectable and the reaction occurs entirely by way of the solvolytic path.<sup>15</sup> The rate of hydrolysis increases by a factor of 5 on going from  $[\text{PtCl}_4]^{2-}$  to  $[\text{AuCl}_4]^-$ .<sup>11,16</sup> The ratio of  $k_2$  for the replacement of the coordinated chloride by bromide in  $[\text{Au}(\text{dien})\text{Cl}]^{2+}$  and  $[\text{Pt}(\text{dien})\text{Cl}]^{2+}$  are  $380$  and  $5.3 \times 10^{-3} \text{ M}^{-1} \text{ sec}^{-1}$ , respectively, at  $25^\circ\text{C}$ ,<sup>16,18</sup> and  $190 \text{ M}^{-1} \text{ sec}^{-1}$  in the monocationic  $[\text{Au}(\text{dien-H})\text{Cl}]^+$  (dien-H = di(2-aminoethyl)-amine that has lost one proton). Furthermore, the reactions of  $[\text{Au}(\text{bipy})\text{Cl}_2]^+$  with amines are faster than those of  $[\text{Pt}(\text{bipy})\text{Cl}_2]^{2+}$ ,<sup>7,17</sup> even though a strict comparison cannot be made because the reactions have not been studied in the same solvent.

One must consider the factors that determine the nucleophilicity of the reagents toward the planar substrates (micropolarizability,  $\pi$  interactions, and basicity), and observe, from the data in Table II, that all of these factors become more important on going from the Pt(II) to the Au(III) substrate. As far as  $\text{Br}^-$  and  $\text{I}^-$  are concerned, the micropolarizability has probably a overwhelming influence upon the nucleophilicity.  $\text{I}^-$  is some 600 times more reactive than  $\text{Br}^-$  toward  $[\text{AuCl}_4]^{2-}$ , whereas the ratio of  $k_2(\text{I}^-) : k_2(\text{Br}^-)$  is only 3.6 in the reactions with  $[\text{PtCl}_4]^{2-}$ . Thus, only does Au(III) act as a "soft" reaction center ( $\text{I}^-$  is a better reagent than  $\text{Br}^-$ ), but it has a greater discriminating ability than Pt(II). The same is true if we compare thiocyanate and bromide since  $k_2(\text{SCN}^-)/k_2(\text{Br}^-)$  is 53 and 1.18, respectively, for reactions with  $[\text{AuCl}_4]^-$  and  $[\text{PtCl}_4]^{2-}$ , although in this case it is not possible to know whether the thiocyanate reacts in the same end in both the transition states.

As far as  $\pi$  interactions are concerned, it should be pointed out that the azide ion has no biphenylic properties when it reacts with a Pt(II) substrate,<sup>2</sup> whereas its electronic properties are quite important in its reactions with Au(III) substrates.<sup>8,9</sup> It also appears that the electronic reagents,  $\text{N}_3^-$  and  $\text{NO}_2^-$ , are characterized, in the reactions listed in Table II, by a low value of  $\Delta S^\ddagger$  and a large negative  $\Delta S^\ddagger$ . This may be due to the stringent stereochemical requirements of the transition states.

The effect of the basicity of the reagent upon its nucleophilicity can be shown to be greater for the Au-complexes by applying eq 2 to corresponding Pt(II) and Au(III) derivatives.<sup>6,7</sup> The Brønsted constant,  $\alpha$ , which is very small when the coordinated chloride in  $[\text{Pt}(\text{bipy})\text{Cl}_2]$  is displaced (0.06),<sup>17</sup> becomes 0.15 for  $[\text{AuCl}_4]^-$  (0.15)<sup>6</sup> and even greater for cationic Au(III) complexes of the type  $[\text{Au}(\text{phen})\text{Cl}_2]^+$  (0.21),

$[\text{Au}(\text{bipy})\text{Cl}_2]^+$  (0.46), and  $[\text{Au}(5\text{-NO}_2\text{-phen})\text{Cl}_2]^+$  (0.89).<sup>7</sup> It should also be noted that, on going from  $[\text{AuCl}_4\text{am}]$  to *trans*- $[\text{Au}(\text{CN})_2\text{Cl}(\text{am})]$ , the *cis* effect of the cyanide ligands is ascribed to a positive inductive effect that increases the amount of negative charge at the reaction center.<sup>9</sup> The anomalously high reactivity of pyridine and even  $\text{CH}_3\text{OH}$  toward  $[\text{AuCl}_4]^-$  might also be ascribed to this effect and to the greater importance of electrostatic effects in general.

All of these results agree well with the original proposal of Baddley and Basolo<sup>5</sup> that the extent to which bond formation develops in the rate-determining transition state is more important in the case of Au(III) than it is in Pt(II). However, it is also clear, mainly from the studies of heterocyclic amines as leaving groups,<sup>8,9</sup> that the extent of bond breaking is also more important for Au(III) than it is for Pt(II). It has now been observed in a number of studies that, although the nature of the leaving group affects the rate of reaction of a Pt(II) complex, it has no effect upon the nucleophilic discrimination factor. For example, it has been shown that, in a series of complexes of the types  $[\text{Pt}(\text{dien})\text{X}]^{2+}$  (X = Cl, Br, I, or  $\text{N}_3$ ), *trans*- $[\text{Pt}(\text{C}_6\text{H}_{11}\text{N}_2\text{NO}_2)\text{X}]^{2+}$  and  $[\text{Pt}(\text{bipy})\text{NO}_2\text{X}]^{2+}$  (X = Cl, Br, I,  $\text{NO}_2$ , or  $\text{N}_3$ ), when ligand X is replaced by a series of nucleophiles, a change of X does not lead to any change in the nucleophilic discrimination factor as measured by  $s$  in eq 1 but only affects the intrinsic reactivity ( $\log k_s$  in eq 1). In other words, plots of  $\log k_2$  against  $n_{\text{Pt}}$  produce a series of parallel straight lines for the different leaving groups in any one series of complexes. This behavior has been interpreted as evidence for a relative independence of the bond-making and the bond-breaking aspects of the substitution. In so far as data are available, it is clear that no such simple relationship exists in the case of the Au(III) complexes, and it has already been pointed out, in the reactions of  $[\text{AuCl}_4\text{am}]$ , where the heterocyclic amine (am) is the leaving group, that not only is the nucleophilic discrimination power of the Au(III) dependent upon the nature of the leaving group but the order of relative nucleophilicity can also be changed.<sup>8</sup> This indicates a much closer interdependence of the bond-making and bond-breaking aspects of substitution. The observation that the reaction rates of the Au(III) complexes appear to be more sensitive than those of Pt(II) to both the nature of the entering group and that of the leaving group is in no way a paradox. The fact that bond making is more important does not, in any way, require that bond breaking is less important, or *vice versa*. It might be possible to approach such a situation, but certainly not reach it, in an associative mechanism when the stability of the five-coordinate intermediate increases sufficiently. In Figure 1 there is a collection of diagrammatic free-energy profiles for a bimolecular reaction showing how the truly synchronous process, with no intermediate, which represents one extreme (A), can develop into one where an intermediate of higher coordination number can form (B) and live long enough to come to thermal equilibrium with its environment. The increasing stability of this intermediate is represented by a deepening of the trough (C), and a situation can be envisaged

vent. The errors introduced by not comparing the data under identical conditions of ionic strength are small compared to those introduced by not comparing them in the same solvent, and even these are small when compared to the magnitudes of the differences we are observing.

Figure 1. Diagrammatic representation of the free-energy profiles for a series of bimolecular substitutions where the stability of the trigonal bipyramidal intermediate increases with respect to the rate-determining transition state from A (no intermediate) to E (stable intermediate).

where the intermediate is more stable than the mixture of the reagents but less stable than the products (D). Finally a situation can be reached where the five-coordinate intermediate is more stable than either form of the four-coordinate system (E) and is not realistically referred to as a substitution reaction. Case A is typical of an  $S_N2$  process involving substitution at a tetrahedral carbon atom. Case D represents a situation recently reported<sup>20</sup> where the addition of amines to  $[C_6H_5RhClSb(p\text{-tolyl})_3]$  results in the rapid formation of a five-coordinate intermediate which then slowly loses the stibine ligand in the rate-determining step to give planar  $[C_6H_5RhCl(am)]$ . The behavior of Pt(II) and Au(III) complexes is represented by a situation between A and D.

We would like to suggest that the progressive stabilization of the five-coordinate intermediate on going from A to E in Figure 1 (provided that this is trigonal

bipyramidal in form) represents the increasing covalency of all five metal-ligand bonds which, in valence-bond terms, could be expressed as the increasing utilization of the fifth orbital in the  $d + s + p^3$  set of the metal. As this intermediate becomes more stable, the process of bond making becomes more and more divorced from that of bond breaking. In the limit, the addition of the incoming group to the complex is affected by the leaving group only in so far as this is one of the four ligands already present in the complex. The process of bond breaking would be affected in the same way by the now entered fifth ligand. In this way both must have some effect upon the reaction rates. However, if the rate-determining transition state is developed before the intermediate,<sup>21</sup> it would be reasonable to expect that the factors leading to the formation of the bond with the incoming group would have a much greater effect upon the rate of reaction than those leading to the subsequent breaking of the bond with the leaving group. If this transition state developed after the intermediate was formed, the reverse situation would obtain. As the intermediate becomes less stable and the mechanism approaches a synchronous process, it no longer becomes possible to divorce bond making from bond breaking and, in the rate-determining transition state, the bond with the incoming group is not fully developed and that with the leaving group is partly broken. It is therefore possible to explain the gross differences between Pt(II) and Au(III) reaction centers by saying that the five-coordinate intermediate developed in the reaction of a gold(III) substrate is less stable, with respect to the rate-determining transition state, than that appearing in the reactions of platinum(II). Both of these are less stable than the intermediate formed in the substitution reactions of planar Rh(I) where, in one case at least, the species can be observed without difficulty. This is in accord with the concept that the utilization of all five orbitals for covalent bonding becomes progressively more difficult as the effective nuclear charge of the central atom increases, i.e.,  $Rh(I) > Pt(II) > Au(III)$ .<sup>22</sup>

*Contribution from the Department of Chemistry, University of North Carolina, Chapel Hill, North Carolina 27514. Received January 20, 1967*

**Abstract:** The magnetic and spectral properties of 1:1 and 1:2 copper(II) halide complexes with substituted quinoline N-oxides have been investigated. The condensed complexes may be divided into three types based on these properties and dependent upon the donor characteristics of the ligands, as measured by their  $pK_a$  values. Members of the first class, containing ligands of relatively high  $pK_a$ 's, display the subnormal magnetic moments typical of the pyridine N-oxide-copper(II) halide systems. Complexes derived from ligands of low  $pK_a$  values constitute the second class, and the third is formed by species of empirical formula  $(CuCl_2)_mL_n$ , where  $1 < m/n < 2$ , containing ligands of intermediate  $pK_a$ 's. Both of these types exhibit normal magnetic moments. The differences in magnetic behavior are correlated with a change in structure from oxygen-bridged to halogen-bridged entities, a conclusion which is supported by far-infrared spectral evidence for the chlorides. The 1:2 complexes all display normal magnetic moments which are temperature independent.

Recently there has been considerable interest in the copper(II) halide complexes of substituted pyridine N-oxides.<sup>2,3</sup> From the observed antiferromagnetic behavior of the 1:1 complex of pyridine N-oxide with copper(II) chloride, the presence of a di- or polymeric species was inferred. This was later substantiated by an X-ray crystallographic examination,<sup>4</sup> where it was shown that the dimeric molecule consists of two distorted tetrahedra sharing an edge with the oxygen atoms of the pyridine N-oxide ligands acting as bridging units. The temperature dependence of the magnetic susceptibility of this and other 1:1 complexes with substituted pyridine N-oxides has been interpreted in terms of a spin-spin coupling occurring *via* a superexchange mechanism through the orbitals of the bridging oxygen atoms. The observed copper-copper internuclear distance of 3.23 Å for the pyridine N-oxide complex is consistent with the super-exchange mechanism. These studies have now been extended to include the magnetic and spectral properties of copper(II) halide complexes with substituted quinoline N-oxides, one of which show extremely interesting and unusual magnetic behavior, not observed with the pyridine N-oxide complexes. A previous communication indicated the preliminary results of our investigations,<sup>5</sup> and these are now reported in full.

## Experimental Section

**Preparation of the Substituted Quinoline N-Oxides.** Quinoline N-oxide, the 4-substituted-quinoline N-oxides, and 6-methylquinoline N-oxide were prepared by the method of Ochiai.<sup>6</sup> Other literature methods were employed for the preparation of 4-chloro-

6-methylquinoline N-oxide,<sup>7</sup> 4-nitro-6-methylquinoline N-oxide,<sup>7</sup> and 3-nitro-6-methylquinoline N-oxide.<sup>8</sup> The melting points of all the ligands were consistent with reported values.

**Preparation of the Complexes.** Method A. In general, the complexes were prepared by mixing a solution of  $CuCl_2 \cdot 2H_2O$  or  $CuBr_2$  in warm ethanol, 2-propanol, or 1-butanol with a stoichiometric amount of the ligand in the same solvent. The products either crystallized immediately or after standing for a short time and were filtered, washed well with the solvent, and dried in the air.

**Method B.** In some cases the use of stoichiometric quantities for the preparation of 1:1 complexes resulted in the isolation of 1:2 species. The condensed complex was then prepared using a tenfold excess of the copper(II) halide in hot 1-butanol as solvent.

**Analytical Data.** Microanalyses for carbon, hydrogen, and nitrogen were performed by Galbraith Laboratories, Inc., Knoxville, Tenn. Copper analyses were determined by EDTA titration using Snazox as indicator.<sup>9</sup> The analytical data are presented in Table I together with the method of preparation of the complexes.

**$pK_a$  Determinations.** The  $pK_a$  values of the ligands were determined spectrophotometrically<sup>10</sup> using the ultraviolet absorption spectra of the free and protonated bases in solutions of known pH. Since the pH values involved were too low to be accurately measured with a pH meter, values of the acidity functions  $H_0$  were employed.<sup>11</sup> The spectra of the two species were compared and significant differences in peak maxima noted. In general, for the neutral, and presumably unprotonated solution of the ligand, one peak was found to increase markedly in intensity from that present in the strongly acidic, protonated solution. The wavelength of this peak was noted. A series of solutions, of pH approximately equal to the estimated  $pK_a$  of the ligand, and differing from each other by 0.2 pH unit, was prepared. The optical densities of these solutions were measured at the wavelength of the above peak, and by comparison with the spectra of protonated and unprotonated species the extent of protonation could be determined. Thus, for each solution a value of the  $pK_a$  of the ligand was obtained and the mean of these results gave the accurate  $pK_a$  value.

**Magnetic Susceptibility Determinations.** Magnetic susceptibilities were determined as a function of temperature by the Faraday method, using equipment and procedures which have been described

previously.<sup>1</sup> Mercury tetrathiocyanatocobaltate(II) was used as magnetic susceptibility standard,<sup>13</sup> and diamagnetic corrections were estimated from Pascal's constants.<sup>13</sup>

**Spectral Measurements.** For the  $pK_a$  measurements ultraviolet absorption spectra were recorded with a Beckman DU spectrophotometer. Diffuse reflectance spectra of solid samples were measured using the standard reflectance attachment and employing a block of magnesium carbonate as standard. Infrared spectra in the range 1300–250  $\text{cm}^{-1}$  were recorded with a Perkin-Elmer 521 double-beam spectrometer.

## Results

**The Complexes.** As the data in Table I show, not all possible complexes were obtained. Thus 2:1 complexes of the ligands 6-methyl-, 4-methyl-, and quinoline N-oxide with both  $\text{CuCl}_2$  and  $\text{CuBr}_2$  did not form, and 4-nitro-6-methyl- and 4-nitroquinoline N-oxide yielded 1:1 adducts only with  $\text{CuCl}_2$ . The use of both methods A and B for the preparation of 1:1 copper(II) chloride complexes with several ligands did not yield the expected products but species of a polymeric nature, as indicated by elemental analyses. Thus both 4-chloro-6-methyl- and 4-chloroquinoline N-oxide afforded compounds of empirical formula  $(\text{CuCl}_2)_2\text{L}_2$  and 3-nitro-6-methylquinoline N-oxide yielded a species which analyzed as  $(\text{CuCl}_2)_4\text{L}_3$ .

**Magnetic Data.** Magnetic susceptibilities were determined at 300, 196, and 77°K only, since these measurements sufficed to distinguish between different types of magnetic behavior. A considerable body of data already exists for the full temperature variation (350–77°K) of the magnetic susceptibility of substituted pyridine N-oxide-copper(II) halide complexes,<sup>2,3</sup> and it was considered unnecessary to repeat these detailed measurements for the quinoline N-oxide derivatives. The magnetic data, together with the observed  $pK_a$

values of the ligands, are presented in Table II. The molar magnetic susceptibilities were calculated on the basis of a molecular weight per copper(II) ion in all cases, and magnetic moments were obtained from the expression  $\mu_{\text{eff}} = 2.84(\chi_m^{\text{cor}}T)^{1/2}$ . It is immediately apparent that the complexes fall into two principal classes. The first class includes the condensed complexes, the majority of which display the low magnetic moments indicative of the binuclear oxygen-bridged unit which has been established for the pyridine N-oxide-copper(II) chloride complex.<sup>4</sup> The second class contains the complexes with a ligand:salt ratio of 2, which all exhibit normal magnetic moments, i.e., a moment greater than or equal to 1.73 BM per copper(II) ion, and which are virtually independent of temperature. The condensed complexes may be further subdivided into those displaying low magnetic moments, the 1:1 species with normal magnetic moments, and thirdly, the compounds of polymeric nature which also show magnetically normal behavior. With the exception of the 3-nitro-6-methylquinoline N-oxide derivative, all the condensed copper(II) bromide complexes exhibit low magnetic moments. It may be significant that no polymeric species are formed when the salt is copper bromide.

**$pK_a$  Data.** The  $pK_a$  values of the ligands lie in the anticipated order, both by comparison with their pyridine N-oxide analogs and on the basis of simple electronic effects. The previously reported value of  $-0.8$  for the  $pK_a$  of 4-nitroquinoline N-oxide<sup>2c</sup> does not agree with our experimental results. However, the value of  $-1.39$  observed here is more consistent with the  $pK_a$  of  $-1.7 \pm 0.15$  reported for 4-nitropyridine N-oxide.<sup>14</sup>

**Far-Infrared Spectra.** Table III records the maxima observed in the spectra of the ligands and their copper(II) chloride complexes in the region 400–250  $\text{cm}^{-1}$ .

the spectra of the 1:1 and 2:1 adducts of pyridine N-oxide with copper(II) chloride are also included. Previous far-infrared spectral studies on complexes containing metal-halogen bonds indicate that metal-chlorine stretching frequencies occur in the range 250–400  $cm^{-1}$  and metal-bromine frequencies from below 400 to 250  $cm^{-1}$ .<sup>15</sup> Thus for the complexes discussed here the observation of infrared-active metal-chlorine stretching frequencies may be anticipated, whereas it is likely that the corresponding metal-bromine vibrations will lie outside the range of the instrument, the lower limit of which occurs at ca. 245  $cm^{-1}$ . Several of the ligands show no absorptions in the range 250–400  $cm^{-1}$ , and consequently the metal-chlorine vibrations may be assigned without difficulty. Although

maxima were observed with some ligands in this region of the spectrum, the bands present in the complexes were considerably more intense and may be assigned as infrared-active metal-chlorine stretching frequencies with a reasonable degree of certainty. Those peaks which are italicized in Table III are assigned as metal-chlorine stretching vibrations. For the copper(II) bromide complexes, as anticipated, the situation is considerably less clear. The region 290–350  $cm^{-1}$  is frequently free of absorptions, further substantiating the assignment of the metal-chlorine stretching frequencies. Below 290  $cm^{-1}$  spectra of all the bromides display an area of increasing absorption and several show maxima at ca. 250  $cm^{-1}$ . However, the bands were very broad and indistinct at this wavelength and are not recorded here.

**Visible Spectra.** The diffuse reflectance spectra of the complexes are summarized in Table IV and representative spectra of the condensed complexes exhibited in Figures 1 and 2. Since the complexes were found to

Figure 1. Diffuse reflectance spectra of three representative condensed copper(II) chloride complexes: —, CuCl<sub>2</sub>-4-methylquinoline N-oxide; ---, (CuCl<sub>2</sub>)<sub>2</sub>-(4-chloro-6-methylquinoline N-oxide)<sub>2</sub>; — · —, CuCl<sub>2</sub>-4-nitroquinoline N-oxide.

decompose in solution, no solution spectra are recorded. The copper(II) bromide complexes were all rather dark in color and several of the 2:1 compounds black. It was necessary to dilute the black compounds with magnesium carbonate in order to obtain a measurable spectrum, and even then only indistinct broad bands were observed. Consequently, the reflectance spectra of the 2:1 adducts of the ligands with copper(II)

bromide are not reported here. Figure 1 includes representative spectra of the three classes of condensed copper(II) chloride complexes. The main feature of interest is the shift in position of the band occurring at 700–900 m $\mu$  dependent upon the class of complex formed. For the compounds displaying low magnetic

moments, the maximum occurs at ca. 750 m $\mu$ , with a shoulder at ca. 875 m $\mu$ , and these are shifted to 850 and 900 m $\mu$ , respectively, in the magnetically normal complexes. In addition, a shoulder at ca. 570 m $\mu$  occurs in the spectra of the polymeric compounds but is absent for the other two classes. With the exception of 3-nitro-6-methylquinoline N-oxide, spectra of the 1:1 complexes of the ligands with copper(II) bromide are

extremely similar. Figure 2 shows a comparison of the spectrum of the copper(II) bromide complex of quinoline N-oxide with that of 3-nitro-6-methylquinoline N-oxide.

## Discussion

**Magnetic Data.** Based on the similarity of the magnetic behavior of the complexes displaying low magnetic moments with that of the copper(II) halide-pyridine N-oxide series, the presence of a similar structure may be inferred, *i.e.*, a dimeric molecule composed of two copper atoms bridged by the oxygen atoms of the N-oxide system. Because of the extremely small forces measured for these complexes with low magnetic susceptibilities, the values of  $\mu_{\text{eff}}$  are only accurate to within 0.1 BM. Thus it is not possible to make any comments concerning the trend of these values. The previously reported 1:1 complexes of this type all exhibit low magnetic moments, with the exception of the copper(II) chloride 4-nitroquinoline N-oxide derivative, which is reinvestigated here. This complex has a room-temperature magnetic moment of 2.13 BM, which is temperature independent. The hitherto unreported 1:1 complex of copper(II) chloride with 4-nitropyridine N-oxide was prepared by mixing a hot 1-butanol solution of the ligand with a large excess of  $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$  dissolved in hot 1-butanol. The product crystallizes as yellow-orange plates and has been characterized by elemental analysis. It shows a room-temperature magnetic moment of 1.01 BM which decreases to 0.33 BM at 77°K.

The normal magnetic moment of  $\text{Cu}(4\text{-nitroquinoline N-oxide})\text{Cl}_2$  has been interpreted in terms of the electronic effects incurred by the introduction of the nitro group to the 4 position of the quinoline ring.<sup>3c</sup> Muto and Jonassen postulate that an electron-attracting entity such as the nitro group will tend to reduce the electron density in the N-O bond (of the quinoline N-oxide system) and consequently the electron density in the  $\pi$  orbitals of the bridging oxygen atom. The interaction between the unpaired electrons in the  $\pi$  orbitals of the copper ions and oxygen  $\pi$  electrons is thus lessened, and the observed magnetic moment will be greater than that of the unsubstituted quinoline N-oxide complex. By this argument the energy difference between the singlet and triplet states is expected to be much greater for the copper(II) chloride complex of 4-nitroquinoline N-oxide than with the quinoline N-oxide derivative itself. The observed magnetic moments indicate that this is the case. However, if the electronic effects of the substituents are the only factors influencing the variation of singlet-triplet splitting energies, then these values for the condensed 4-nitroquinoline N-oxide and 4-nitropyridine N-oxide-copper(II) chloride complexes should be of comparable magnitude. The observed room-temperature magnetic moments of 2.13 and 1.01 BM, respectively, indicate that this is not so and that the "electronic" effect of 4-nitroquinoline N-oxide is considerably greater. Thus it becomes apparent that additional factors should be taken into consideration.

An alternative approach is to consider the increased steric requirements of the quinoline N-oxide system when compared with pyridine N-oxide. It is possible that the decreased donor strength of 4-nitroquinoline N-

oxide with respect to the unsubstituted quinoline N-oxide, *coupled* with the steric factors, cause a change in the structural properties of the molecule. It has been shown that binuclear species formed by bridging copper ions with chloride ions do not tend to be diamagnetic,<sup>16</sup> and thus a structure containing chloride bridges rather than oxygen bridges would account for the observed magnetic properties.

Thus for the condensed copper(II) chloride complexes, ligands with relatively low donor strengths, *i.e.*, very low  $pK_a$  values, would give rise to chloride-bridged species, whereas ligands with high donor strengths afford the usual oxygen-bridged species. For ligands of intermediate donor strengths a third class of compound is formed, members of which display a high magnetic moment and possess polymeric, halogen-bridged structures.

All the 1:1 copper(II) bromide complexes prepared in this study, with the exception of the 3-nitro-6-methylquinoline N-oxide derivative, exhibited low magnetic moments. The one exception possibly contains bromide bridges. No compounds of polymeric nature are formed with copper(II) bromide, and this may be due to the reduced tendency of the bromide ion, as compared with the chloride ion, to act as a bridging group.

The magnetic properties of the 4-nitropyridine N-oxide-copper(II) chloride complex may be explained solely in terms of the electronic effects of the substituent, and no change in structure from the oxygen-bridged parent compound of the series need be invoked.

Both copper(II) chloride and copper(II) bromide complexes with two molecules of the substituted quinoline N-oxide exhibit normal magnetic moments which are virtually independent of temperature.

**Far-Infrared Spectra.** The far-infrared spectral data provide support for the suggestion that there is a structural difference between the classes of condensed complexes. In this discussion it should be recognized that the terms "terminal" and "bridging" are used only in a relative sense. It is probable that a chloride ion bonded directly to one copper ion will interact to some extent with neighboring copper ions and in such a sense could then be termed as bridging. However, for our purposes a terminal chlorine atom is defined as one which is bonded to a copper ion when the binuclear oxygen-bridged species is known to be present, and a bridging chloride ion as one which is bridging two copper ions to form a dimeric or polymeric molecule. Two distinct types of bridging chlorine atoms may be envisaged: firstly, those which are symmetrically disposed between the two copper atoms giving equal bond lengths and, secondly, those which are unsymmetric giving rise to one short and one long copper-chlorine bond distance.

Although the literature contains numerous references to metal-chlorine vibrations of bridging chlorine atoms in copper(II) chloride complexes, the evidence for terminal copper-chlorine stretching frequencies is rather meager, presumably owing to the lack of suitable compounds. Thus the complex  $\text{Cu}(\text{pyridine})_2\text{Cl}_2$  is polymeric in the solid state and its structure composed of distorted octahedra connected by bridging chlorine atoms.<sup>17</sup> In each octahedron there are two long (3.05

A) and two short (2.28 Å) copper–chlorine bonds. In the far-infrared spectrum of this compound, absorptions attributed to copper–chlorine stretching vibrations occur at 228 and 287  $\text{cm}^{-1}$ , and these probably represent the vibrations of the long and short bonds, respectively.<sup>18,19</sup> Conversely, for steric reasons, the complex  $\text{Cu}(\text{quinoline})_2\text{Cl}_2$  cannot contain two bridging chlorine atoms of the above type since the presence of the quinoline ring results in a copper–chlorine “long” bond distance too great to give rise to a stretching frequency.<sup>18</sup> Thus the assignment of a copper–chlorine stretching mode at 330  $\text{cm}^{-1}$  should represent the vibration of the copper–chlorine “short” bond, which is also bridging in character. The addition of substituents adjacent to the nitrogen atom in pyridine complexes of this type has a pronounced effect on the metal–halogen stretching frequency;<sup>18,20</sup> on substituting the 2 and 5 positions with various groups, the maxima are found to occur in the range 323–309  $\text{cm}^{-1}$ , whereas, for substituents in the 3 and 4 positions, corresponding peaks occur at 294–278  $\text{cm}^{-1}$ . Recently a report of the far-infrared spectra of some substituted quinoxaline derivatives of copper(II) halides indicates that for these compounds terminal metal–chlorine bonds show absorptions at 368–337  $\text{cm}^{-1}$ , and bridging bonds occur at ca. 320  $\text{cm}^{-1}$ .<sup>21</sup>

Considering the available evidence, it becomes apparent that the values of metal–chlorine stretching frequencies are very dependent upon the ligand used, even when the structures of the complexes are thought to be the same. However, as a rough guide, the dividing line between bridging and terminal metal chlorine stretching frequencies may be considered to lie at ca. 330–340  $\text{cm}^{-1}$ .

The structure of the 1:1 complex of pyridine N-oxide is known to contain copper–chlorine bonds which do not interact with any neighboring copper atoms,<sup>4</sup> and thus these are terminal in character. The far-infrared spectrum of this complex shows maxima at 311 (vs) and 330  $\text{cm}^{-1}$  (w, sh) which may be attributed to copper–chlorine stretching frequencies. Thus for the quinoline N-oxide complexes, we may infer that the observation of metal–chlorine stretching vibrations at frequencies higher than, say, 320  $\text{cm}^{-1}$  indicates the presence of terminal metal–chlorine bonds and hence oxygen-bridged structures.

For clarity, maxima assigned as metal–chlorine stretching vibrations in the condensed copper(II) chloride–quinoline N-oxide complexes are summarized in Table V. In the compounds with low magnetic moments and presumably oxygen-bridged structures, maxima observed at ca. 330 and 340  $\text{cm}^{-1}$  are assigned as terminal metal–chlorine stretching frequencies. These bands are absent in the spectra of complexes with normal magnetic moments and here two peaks at ca. 280 and 300  $\text{cm}^{-1}$  are observed in all cases. This significant shift to lower wavelength, which correlates with the change in magnetic properties, is considered to reflect the difference between structures containing terminal and bridging metal–chlorine bonds. In support of this conclusion the magnitude of the shift, ca.

<sup>a</sup> w = weak, m = medium, s = strong intensity; v = very and sh = shoulder

35–45  $\text{cm}^{-1}$ , is of a similar order to that observed with the quinoxaline complexes mentioned above.<sup>21</sup>

X-Ray crystallographic evidence for the 2:1 complex of pyridine N-oxide with copper(II) chloride shows the presence of the same basic structure as in the corresponding 1:1 species.<sup>22</sup> In the far-infrared spectrum of the former complex, two metal–chlorine stretching frequencies are observed at 310 and 286  $\text{cm}^{-1}$ . Although the oxygen bridged unit is still present, the inclusion of an extra pyridine N-oxide ligand into the coordination sphere of each copper ion presumably has the effect of weakening the metal–chlorine bonds, thus causing a reduction in the metal–halogen stretching frequencies.

Since this compound displays a subnormal magnetic moment, whereas all the 2:1 quinoline N-oxide complexes show normal magnetic properties, it is not possible to effect comparisons. However, in view of the magnetic results and the relatively low metal–halogen stretching frequencies, it seems likely that the latter compounds possess polymeric halogen-bridged structures.

Spectra of the 2:1 derivatives with ligands containing nitro groups show only one band attributable to a metal–chlorine stretching vibration, and these occur at slightly higher frequencies than the mean value of 300  $\text{cm}^{-1}$  for complexes not containing nitro substituents. In particular, the 3-nitro-6-methylquinoline N-oxide complex shows a maximum at 342  $\text{cm}^{-1}$ . The explanation of this is not clear.

**Visible Spectra.** The spectra of the condensed copper(II) chloride complexes may be divided into two main band systems, the first occurring at 350–450  $\text{m}\mu$  and the second at 700–850  $\text{m}\mu$ , of which the relative intensity of the latter is considerably less. The first band system is probably associated with charge-transfer transitions, and the second may be attributed to transitions within the d shell. Most of the bands are obviously multiple in character, and an indistinct shoulder is observed in all cases at about 900  $\text{m}\mu$  on the side of the lower energy band. The shift in position of the maximum associated with the d–d transition, which correlates with the differences in magnetic proper-

ties of the complexes, probably reflects the differing environments of the copper ion in the two cases.

Except for the appearance of an intense band at *ca.* 500  $m\mu$ , spectra of the 1:1 copper(II) bromide derivatives are essentially similar to those of the chlorides displaying low magnetic moments. Also, the shoulder at 900  $m\mu$  is more pronounced in the case of the bromides. The origin of the 500- $m\mu$  band is uncertain, although as seen in Figure 1 spectra of the chlorides do show shoulders of much weaker relative intensity in this region. As with the condensed chloride complexes with high magnetic moments, the spectrum of the 1:1 copper(II) bromide-3-nitro-6-methylquinoline N-oxide derivative is significantly different from those of the corresponding complexes displaying low magnetic moments. As indicated in Table IV, the d-d band is shifted from *ca.* 730  $m\mu$  down to 790  $m\mu$  in the bromide-bridged species. This again is probably an indication of the different environments of the copper ion in the oxygen-bridged and bromide-bridged species.

The spectra of the 2:1 complexes with copper(II) chlorides show similar features to those of the con-

densed complexes. The maxima due to transitions within the d shell are shifted to slightly higher energy in the 2:1 derivatives.

## Conclusion

The spectral and magnetic properties of the condensed copper(II) halide complexes of substituted quinoline N-oxides indicate that either oxygen-bridged or halogen-bridged derivatives may be formed. The experimental evidence indicates that there must be a critical relationship between such factors as the donor properties and steric requirements of the ligands and the lattice energies of the various compounds in favoring the formation of one species over another.

# The Dissociative Interchange Mechanism for the Formation of Acidopentaamminecobalt(III) Ions<sup>1</sup>

Cooper H. Langford and Warren R. Muir

*Contribution from the Moore Laboratory of Chemistry, Amherst College, Amherst, Massachusetts 01002. Received January 21, 1967*

**Abstract:** The rates of formation of the complex ions,  $\text{Co}(\text{NH}_3)_5\text{X}^{n+}$ , are discussed with special attention to the rate of reaction in the outer-sphere complex (or ion pair)  $\text{Co}(\text{NH}_3)_5\text{OH}_2^{3+} \cdots \text{X}^{(3-n)-}$ . (New data are presented for entry of chloride and thiocyanate ions at 45° and unit ionic strength.) It is observed that the rates are similar for all anions studied so far and are a nearly constant fraction (0.2) of the water exchange rate for  $\text{Co}(\text{NH}_3)_5\text{OH}_2^{3+}$ . These results may be understood in terms of an activation process which is *dissociative*, leading to a *transition state* in which entering and leaving ligands are at most weakly bound *but* in which no intermediate of significant lifetime is formed. The similarity of rates of entry implies weak binding in the transition state. The anion entry rates appear to be related to the water exchange rate through a statistical factor connected with the probability that an anion is to be found in an outer coordination sphere site when a cobalt-water dissociation event occurs.

This paper is concerned with the kinetics and equilibrium of reaction 1, where X is a univalent anionic ligand or sulfate and *n* is 2 or 1, respectively. Two

mechanistic pathways for this process have often been discussed, and neither seems to give an entirely felicitous account of the details. In one case,<sup>2</sup> the process has been regarded as a simple nucleophilic attack of the entering group on the complex, leading to a concerted substitution which is bimolecular and adequately represented by eq 1. The alternative account<sup>3</sup> suggests

the participation of five-coordinate intermediate of the pathway represented by

The kinetics of eq 2 require the prediction that X and H<sub>2</sub>O compete for the intermediate. Strong evidence against eq 2 was presented by Pearson and Moore<sup>4</sup> who were able to show for the case of X = Br<sup>-</sup> or NO<sub>2</sub><sup>-</sup> that addition of SCN<sup>-</sup> to the solution did not lead to any detectable direct production of  $\text{Co}(\text{NH}_3)_5\text{NCS}^{2+}$ . The experiment is conclusive because sufficient kinetic and equilibrium data are available to predict<sup>3</sup> the rate of capture of the intermediate by SCN<sup>-</sup> if the reaction were going by mechanism 2.

The alternative account which focuses attention on the bimolecularity of the substitution is unsatisfactory in the

sense that studies of structure variation (e.g., a linear free-energy relationship between rates and equilibria as the leaving group is varied<sup>6</sup>) strongly imply a transition state for the reaction with at most very weak bonds to the participating ligands.

Here, we wish to *explore* the applicability of a mechanistic scheme which assumes that the transition state is reached *dissociatively* but assumes *no* intermediate along the reaction pathway of *sufficient stability to be selective in its reactions*. We assume that the transition state must incorporate a ligand from its immediate solvation shell (outer coordination sphere) so that although activation is dissociative the reaction is "accidentally bimolecular." The entering group must be present in advance of the transition state. Such a scheme is designated "dissociative interchange"<sup>6</sup> ( $I_d$ ), dissociative to denote the activation process and interchange to indicate that the substitution process is a rearrangement between inner and outer coordination spheres (a process first discussed by Alfred Werner). The  $I_d$  mechanism is shown in eq 3 for the complex formation reaction.

Note that the degree of ion association characterized by the association constant  $K_a$  is quite important and, if the activation process is genuinely dissociative, the rate constant,  $k$ , should be independent of the nature of the entering group. There is an additional important prediction from this scheme. In a simple 1:1 outer-sphere complex (ion pair),  $s - 1$  of the outer-sphere sites will be occupied by solvent (water) molecules if  $s$  is the solvation number of the complex. If the anionic partner occupies outer-sphere sites randomly, dissociation of the coordinated water will not normally occur adjacent to the anion;  $(s - 1)/s$  dissociative events will lead to water exchange and only a fraction,  $1/s$ , will lead to anation. Thus, the  $I_d$  mechanism predicts that anations occur at very nearly the *same rate* in 1:1 outer-sphere complexes as the nucleophilicity of the entering group is varied *but* that all anations occur at approximately  $1/s$  times the rate of solvent exchange.

## Experimental Section

**Materials.** The complexes  $[\text{Co}(\text{NH}_3)_5\text{Cl}][\text{ClO}_4]_2$ ,  $[\text{Co}(\text{NH}_3)_5\text{NCS}][\text{ClO}_4]_2$ , and  $[\text{Co}(\text{NH}_3)_5\text{OH}_2][\text{ClO}_4]_2$  were prepared by well-known methods<sup>7</sup> and characterized spectrophotometrically. Extinction coefficients at wavelengths important to this study are collected in Table I. Reagent grade sodium chloride and sodium thiocyanate were used without further purification. Sodium perchlorate solutions for ionic strength control were prepared by titration of standardized concentrated sodium hydroxide solutions with perchloric acid and dilution to the required volume. Stock solutions of sodium chloride, sodium perchlorate, and water used in preparing reaction mixtures were adjusted to pH 3 by addition of perchloric acid to repress acid dissociation of  $\text{Co}(\text{NH}_3)_5\text{OH}_2^{2+}$  (in experiments with thiocyanate, the pH was adjusted to 5).

**Equilibrium Studies.** The equilibrium between  $[\text{Co}(\text{NH}_3)_5\text{Cl}]^{2+}$  and  $[\text{Co}(\text{NH}_3)_5\text{OH}_2]^{2+}$  was studied at 45.0° as a function of NaCl

**Table I.** Some Features of Visible Spectra of Complexes Used in This Study (Absorption Maxima and Wavelengths Used in Reaction Studies)

Complex	$\lambda_{\text{max}}$ , mμ	$\epsilon_{\text{max}}$ , M <sup>-1</sup>	$\lambda$ , mμ	$\epsilon$ , M <sup>-1</sup>	Ref
$\text{Co}(\text{NH}_3)_5\text{Cl}^{2+}$	532	50.7	555	44.0	This work 6b, 10
	532	51.0	...	...	
$\text{Co}(\text{NH}_3)_5\text{OH}_2^{2+}$	491	48.6	555	18.2	This work 6b, 10
	491	47.5	...	...

concentration in a medium maintained at an ionic strength of 1.00 with  $\text{NaClO}_4$  (pH 3) and in a medium of variable ionic strength (no  $\text{NaClO}_4$ , pH 3). Solutions maintained in constant-temperature baths for more than seven half-lives of the approach to equilibrium reaction were quenched to 25° and examined spectrophotometrically in 5.00-cm cells on a Beckman DU equipped with a Gilford photometer unit or in 1.00-cm cells on a Cary Model 14 equipped with a 0.0–0.2-absorbance unit slidewire. Total cobalt complex concentrations were chosen in the range from  $5 \times 10^{-4}$  to  $1.5 \times 10^{-3}$  M. Sodium chloride concentrations were varied from 0.03 to 0.7 M. The wavelengths examined were 555 and 530 mμ.

**Kinetic Studies.** The rate at which reaction 1 approaches equilibrium was examined in the case that  $\text{X} = \text{Cl}^-$  in the same media as those employed in the equilibrium studies. The experiments were carried out at 45.0° in the thermostated cell chamber of a Cary 14 spectrophotometer using 1.00-cm cells and a 0.0–0.2-absorbance unit slidewire. Good pseudo-first-order rate plots were obtained over more than two half-lives of the reaction. Rates of the reaction of  $[\text{Co}(\text{NH}_3)_5\text{OH}_2]^{2+}$  with thiocyanate (which goes to "completion") were examined under similar conditions except that the pH was 5, the spectrophotometer was a Beckman DU, and the wavelength used was 490 mμ.

**Ion-Association Study.** The extent of association between  $\text{Co}(\text{NH}_3)_5\text{OH}_2^{2+}$  and  $\text{Cl}^-$  was explored by analysis of the enhancement of ultraviolet absorption by the complex at 230 mμ at 25° (pH 3,  $\mu = 1.00$ ). Data were analyzed by the method of Newton and Arcand as employed by Evans and Nancollas.<sup>8</sup> The concentration of the cobalt complex was  $1 \times 10^{-4}$  M, and the chloride concentration was varied from 0.003 to 0.5 M.

## Results

The first column of Table II presents the equilibrium concentration ratio  $[\text{Co}(\text{NH}_3)_5\text{OH}_2^{2+}]/[\text{Co}(\text{NH}_3)_5\text{Cl}^{2+}]$  as a function of chloride concentration. Rates of approach to equilibrium are also collected in Table II.

and the anation rates in Figure 2. Since anation by thiocyanate ion goes to completion, only anation is given. They appear in Figure 3.

According to the dissociative interchange mechanism described in eq 3, the chloride or thiocyanate dependence ( $X^-$  dependence) of the observed pseudo-first-order rate constants,  $k'$ , is given by eq 4, which employs

$$k' = \frac{kK_a[X^-]}{1 + K_a[X^-]} \quad (4)$$

notation of (3). The distinct curvature in Figures 2 and 3 indicate that the term  $K_a[X^-]$  is not small.

A trial-and-error analysis based on a least-squares criterion was employed to find best choices of the parameters  $K_a$  and  $k$ , the outer-sphere association constant, and rate constant for interchange, respectively. Values of the parameters with the associated standard deviations are given in Table III along with interchange rate constants from the work of Taube and his collaborators.<sup>6b,10</sup>

$[\text{Cl}^-]$  against  $A$ , where  $A$  is the absorbance at a given  $[\text{Cl}^-]$  and  $A_0$  is the absorbance in the absence of chloride, should be linear with the slope equal to  $-K_a$  and the intercept equal to  $K_a A_1$ , where  $A_1$  is the absorbance of the ion pair.<sup>7</sup> This plot is shown in Figure 4. The

slope yields a value of  $K_a = 3.2 \pm 0.3$  in good agreement with the value from analysis of kinetic data and with values obtained at other wavelengths. Note that the results of Evans and Nancollas<sup>8</sup> suggest that the result should be insensitive to temperature, a view which receives direct support from equilibrium studies of the  $\text{Co}(\text{NH}_3)_5\text{OH}_2^{2+}$ -chloride system reported elsewhere.<sup>11</sup>

## Discussion

**1. The Importance of Ion Association.** Since the extent of ion association between triply charged cobalt ammine complexes and simple anions has been a subject of some controversy,<sup>12</sup> we note that substantial *specific* ion effects are seen in all of the equilibrium and kinetic curves. This would seem to justify the approach adopted here. Additional support is derived from independent spectrophotometric measurement of outer-sphere association between  $\text{Co}(\text{NH}_3)_5\text{OH}_2^{2+}$  and  $\text{Cl}^-$  which gives a value of  $K_a = 3.2$  at  $25^\circ$  and unit ionic strength in reasonable agreement with the value in Table III. However, *it must be emphasized that the "constants" reported are in no sense thermodynamic equilibrium constants.* They simply provide a convenient measure of the extent of ion association in these media and indicate anion concentrations at which the equilibrium is "saturated" and a limiting rate for complex formation is reached.

**2. The Values of "Limiting" Complex Formation Rates.** Compare the first-order rate constants in Table II. The limiting rates for complex formation for the outer-sphere complexes  $\text{Co}(\text{NH}_3)_5\text{OH}_2^{2+} \cdots \text{SO}_4^{2-}$  and  $\text{Co}(\text{NH}_3)_5\text{OH}_2^{2+} \cdots \text{H}_2\text{PO}_4^-$  are reasonably accurately known since the association constants,  $K_a$ , proved large enough to permit fairly unambiguous determinations. They are seen to differ by a factor of about 2, being respectively 0.24 and 0.13 times the water exchange rate. In order to assess the role of the entering group in the transition state for complex formation, it was desirable to obtain similar rate constants for significantly different entering groups. The values have proved more difficult to obtain because of smaller  $K_a$  values and are presumably less accurately determined. But, the values for  $\text{Co}(\text{NH}_3)_5\text{OH}_2^{2+} \cdots \text{Cl}^-$  and  $\text{Co}$ -

$(\text{NH}_3)_5\text{OH}_2^{2+} \cdots \text{NCS}^-$  are estimated to be 0.21 and 0.16 times the water exchange rate. Thus, the variation in these first-order rate constants is *less than a factor of 2* for formation of a series of complexes differing in stability by about two powers of ten. That is, with nucleophiles of charge  $-2$  or  $-1$  and donor atoms varying on Cl, O, and N, only very small rate differences are detected. These results lend substantial support to the view that the absence of a five-coordinate intermediate in these reactions does not imply assistance from an entering nucleophile in the activation process. Activation is apparently dissociative (d).

**3. Comparison to Water Exchange Rate.** The most striking feature of the results is that *all* complex formation rates are *less than* the water exchange rate by a factor near 5. Since anion entry rates are so similar, this might be considered surprising, but it is easily rationalized under the idea of dissociative interchange ( $I_d$ ). If the transition state is reached by very substantial weakening of the bond to the leaving group but the system does not have access to any reasonably stable five-coordinate state, it must stabilize by adding the immediately available ligand. Since the majority of outer-sphere sites are still occupied by water molecules in the 1:1 outer-sphere complex (ion pair) between  $\text{Co}(\text{NH}_3)_5\text{OH}_2^{2+}$  and an anion, the most probable fate of an activated complex is recombination with an outer-sphere water molecule. Except in the study of water exchange (when all outer-sphere sites are occupied by water), water exchange is an undetectable, fruitless process. Thus, anion entry (complex formation) is expected to proceed at a rate less than water exchange and governed by the probability that the anion in the 1:1 outer-sphere complex occupies the site adjacent to the leaving inner-sphere water molecule. The factor of 5 seems reasonable.

Finally, it is important to note that the relationship between interchange complex formation rates and solvent exchange rates discussed for the  $\text{Co}(\text{NH}_3)_5\text{OH}_2^{2+}$  system is not an isolated example. Murray and Barraclough observed a sulfate entry rate 0.25 times the water exchange rate for formation of *cis*- $\text{Co}(\text{en})_2\text{OH}_2^+$ - $\text{SO}_4$ ,<sup>13</sup> and Earley and Duffy<sup>14</sup> observed entry rates for chloride and thiocyanate of about 5% of the water exchange rate in studies of formation of  $\text{Cr}(\text{NH}_3)_5\text{X}^{2+}$  ( $\text{X} = \text{Cl}^-, \text{SCN}^-$ ).

## Bis(pyridine)boronium Salts. Syntheses and Formation Kinetics

G. E. Ryschkewitsch

*Contribution from the Department of Chemistry, University of Florida, Gainesville, Florida 32601. Received August 11, 1966*

**Abstract:** Salts of bis(pyridine)boronium ion have been synthesized in pyridine by four routes: from trimethylamine borane and iodine, from trimethylamine borane and bis(pyridine)mercury(II) chloride, from sodium borohydride and iodine, and from trimethylamine chloroborane. In addition, the B-deuterated ion has been prepared. The reaction between trimethylamine borane and iodine exhibits a deuterium isotope effect, which was established from competitive rates and from the reaction rates of the hydrogen and deuterium compounds ( $k_H/k_D = 2.0$ ). A reaction mechanism is discussed.

Boronium salts, where two tertiary amines are coordinated to a  $BH_3^+$  group, have been reported by Muetterties.<sup>1</sup> The basic structure was produced from an amine borane by reaction with an ammonium salt or, alternately, with diborane or  $B_{12}H_{12}^{2-}$  salts. Either method requires relatively high temperatures and the use of high pressure. In our hands, the first method proved to be quite sensitive to reaction conditions, producing yield-reducing side reactions. The second method suffers from relatively low yields (~25%) and from the convenience of handling a reactive gas or preparing the intermediate borane anion.

We wish to report several new synthetic approaches to boronium salts, exemplified by the bis(pyridine)boronium ion, which allow synthesis from readily obtained starting materials, under mild and convenient conditions, and in high yield.

## Experimental Section

**Materials.** Trimethylamine borane was used as obtained from Callery Chemical Co. Some lots were purified by sublimation. Sodium borohydride and sodium borodeuteride were supplied in good purity by Metal Hydrides, Inc. All other compounds were reagent-grade materials and were used without further purification. Trimethylamine monochloroborane was prepared in 50% yield from trimethylamine borane and concentrated aqueous HCl mixed with benzene.<sup>2,3</sup> It was recrystallized from  $CCl_4$  by slow addition of hexane: mp 82–84°, lit.<sup>4</sup> 85°. Alternately, the material could be prepared by passing anhydrous HCl into a trimethylamine borane solution in benzene.

Diborane- $d_6$  was prepared on the vacuum line from 1 g of sodium borodeuteride and boron trifluoride in diglyme solution.<sup>5</sup> The gas was allowed to react with excess trimethylamine to afford deuterated trimethylamine borane. After vacuum sublimation it melted sharply at 91°. The infrared spectrum agreed well with the published data.<sup>6</sup> The relative proportions of B–H and B–D bonds were established by comparison of the absorbancies at 2370 and 1790  $cm^{-1}$  after calibration with a known mixture. The compound was 93% deuterated.

**Preparation of Bis(pyridine)boronium Ion. From Trimethylamine Borane and Iodine.** Trimethylamine borane, 3.64 g (50.0 mmoles), was dissolved in 30 ml of pyridine, and solid iodine, 12.7 g (50.2 mmoles), was added in small portions over a 15-min period. An exothermic reaction started immediately and was finished after 1 hr while warming the mixture gradually to a final temperature of 70°. After cooling, the precipitate of trimethylammonium iodide was filtered off, and the filtrate was evaporated at room temperature,

affording 14.7 g of bis(pyridine)boronium iodide (99% yield). The ammonium salt after washing with benzene and a small amount of ether weighed 8.75 g (94% yield). The identity of the ammonium salt was established by its infrared spectrum and its iodide analysis. Reaction had thus proceeded according to the equation

**2. From Trimethylamine Borane and Bis(pyridine)mercury(II) Chloride.** Trimethylamine borane, 3.76 g (56 mmoles), and mercury(II) chloride, 13.06 g (48.1 mmoles), were heated with 50 ml of pyridine to light reflux for 5 hr. During this period the solution turned cloudy and eventually deposited liquid mercury. After filtering off the metallic mercury (9.266 g, 96% recovery), 20 ml of benzene and 20 ml of carbon tetrachloride were added to the filtrate, yielding 14.42 g of light yellow solid as a precipitate. On adding excess potassium hexafluorophosphate to a water solution of this solid there was recovered, after washing with water and ether, 5.40 g (26.2 mmoles) of  $(C_5H_5N)_2BH_3PF_6$  for a 55% yield of boronium salt. The compound was identical in spectrum and melting point with preparations from the iodide salt.

**3. From Sodium Borohydride and Iodine.** (a) Sodium borohydride (94% hydride purity), 1.80 g (44.8 mmoles), was slurried with 25 ml of pyridine. While this solution was stirred in an ice bath, an 0.00984 M iodine solution was very slowly added. The iodine color was discharged immediately while a gas, presumably hydrogen, evolved. After 22.5 ml (22.2 mmoles) of iodine solution had been added, the reaction rate of iodine decreased abruptly and gas evolution ceased. The solution was now heated while more iodine was added; a persistent iodine color was obtained after an additional 44.5 ml (43.7 mmoles) of iodine solution had been added. The amounts of iodine used correspond closely to the quantities calculated from the equations representing two successive and separated reactions steps.

(b) Accordingly, in a similar experiment, the reaction was stopped after the first stage, the excess pyridine was evaporated, and the resulting residue of white solid and yellow liquid was extracted with carbon tetrachloride. After evaporation of the solvent there was obtained a 99% yield of pyridine borane, identical in infrared spectrum with an authentic sample. The solid, insoluble in carbon tetrachloride, was sodium iodide contaminated with water and pyridine.

Bis(pyridine)boronium iodide was isolated from reaction 3 by precipitating it with carbon tetrachloride. Preparations by this procedure always contained varying amounts of carbon tetrachloride which could not be removed by pumping.

**4. From Trimethylamine-Monochloroborane.** Trimethylamine monochloroborane, 0.551 g (5.19 mmoles), was refluxed with 15 ml of pyridine for 45 min. The mixture was evaporated to dryness and the water-soluble residue (0.954 g) was converted to the hexafluorophosphate salt by precipitation with excess  $NH_4PF_6$  in 15 ml of water (crude yield, 0.936 g). A portion of this was recrystallized from water to give pure  $(C_5H_5N)_2BH_3PF_6$ , mp 114.5–115°, in 41%

recovery. The maximum yield of chloride salt, according to the eq 4 was thus 88%; the minimum over-all yield of pure  $PF_6^-$  salt was 25%.

**Derivatives.** The halide salts are very soluble in water as well as in many organic solvents (alcohols, acetone, acetonitrile, chloroform, methylene chloride) but insoluble in carbon tetrachloride, ether, or pentane. The complex fluorides show similar solubility relations but are much less soluble in cold water.

The halides readily absorb water from the atmosphere. The anhydrous iodide (0.5143 g, 1.72 mmoles) was exposed in a closed container to saturated water vapor at room temperature. After 30 hr the sample had come to constant weight, 0.5438 g. The calculated weight for a monohydrate is 0.5453 g. Simultaneously there appeared in the infrared spectrum a doublet at 3500 and 3430  $cm^{-1}$  and a sharp band at 1580  $cm^{-1}$ , and two bands at 760 and 740  $cm^{-1}$ . The first three bands apparently correspond to the stretching and bending modes of water, respectively, whereas the latter two absorptions may be caused by librational modes of lattice water.<sup>7</sup> The absorbed water could be removed quantitatively by evacuation over  $P_2O_5$ .

The iodide or chloride was readily converted to the less soluble perchlorate (mp 97–99°), hexafluorophosphate, or hexafluoroarsenate by precipitating these salts from aqueous solution with  $NaClO_4$ ,  $NH_4PF_6$ , or  $KAsF_6$ , respectively. The latter two salts are easily recrystallized from hot water. The chloride salt was obtained from the iodide by reaction with a slight excess of mercury(II) chloride in aqueous solution, which resulted in precipitation of  $HgI_2$ . Excess  $Hg^{2+}$  was removed immediately by shaking with metallic mercury in order to avoid oxidation of the boronium ion. On evaporation of the filtered solution, the chloride was obtained in 30% yield as the hydrated salt, mp 59–62°.

On shaking aqueous solutions of the iodide with  $CCl_4$ , there resulted a white precipitate which proved to be very similar to the product obtained when the boronium salt was precipitated with  $CCl_4$  from pyridine solution. The materials showed all the infrared absorption bands of the pure boronium salt but contained from 0.25 to 0.9 mole of  $CCl_4$  per mole of  $(C_5H_5N)_2BH_2I$ . Carbon tetrachloride could be removed either by heating under vacuum above the melting point (110–125°) or by distilling a solution; depending on the water content of the system, either the hydrate or the anhydrous salt was thus obtained.

**Preparation of Deuterated Bis(pyridine)boronium Hexafluorophosphate.** Trimethylamine borane- $d_3$  (1.00 mmole) in 5 ml of pyridine was allowed to react with iodine (0.98 mmole) for 40 hr at 25°. After evaporating the solvent below room temperature, the resulting iodide salt was converted to the hexafluorophosphate derivative in the usual manner. The amount of deuteration on boron in the recrystallized product (mp 114.5–115°) was the same as in the starting material, as evidenced by the infrared spectrum.

In an abortive attempt to deuterate the boronium salt by exchange, 1.15 mmoles of the iodide salt was dissolved in 1 ml of  $D_2O$ ; the relative intensity of the B–H absorption at 2480  $cm^{-1}$  remained unchanged over 24 hr. at room temperature. Neither did there appear an absorption at 1900  $cm^{-1}$ , characteristic of B–D, even when a solution acidified (pH ~1) with thionyl chloride was left at room temperature for 3 days.

**Characterization.** All the boronium salts had similar infrared spectra, except for the expected differences caused by the known absorptions of the complex anions. The main features are the two bands, 2480 and 2380  $cm^{-1}$ , showing relatively high wavenumbers for B–H bonds, which are shifted to 1900 and 1760  $cm^{-1}$ , respectively, in the deuterated compound. The B–H deformations appear at

1160 (B–D, 915) and 1065  $cm^{-1}$  (B–D, probably masked by anion and solvent absorptions). In addition, a sharp absorption at 1640  $cm^{-1}$  indicates the presence of the pyridine ring.

In the ultraviolet spectrum there are three bands in all the salts with similar molar absorptivities,  $a$ : 2538 Å,  $a = 6.90 \times 10^4$ ; 2591 Å,  $a = 7.58 \times 10^4$ ; 2657 Å,  $a = 5.01 \times 10^4$ . Elemental analyses are given in Table I.

The cation, like the bis(trimethylamine) compound previously reported,<sup>1</sup> is stable toward acid or base; no change in the ultraviolet spectrum was noticed in 0.1 M HCl or 0.1 M NaOH, even after a week at room temperature.

The  $B^{11}$  nuclear resonance spectra were kindly obtained by Dr. Brey of this department at 19.3 Mc in  $CH_2Cl_2$ . The undeuterated and deuterated salts showed identical shifts of +16.2 ppm relative to trimethyl borate. Because of the broadness of the resonance, the B–H and B–D coupling constants could not be determined.

The proton spectrum, obtained with a Varian A-60A spectrometer at ambient temperature, showed the expected pattern for the pyridine-ring hydrogens: a doublet, a triplet, and a triplet with relative integrated intensities of 2.0:1.0:2.0. The resonances had considerable fine structure and were, in water solution, centered about -8.78, -8.35, and -7.35 ppm, respectively, relative to external tetramethylsilane. In  $CDCl_3$  with internal tetramethylsilane, the resonances appeared at -9.08, -8.38, and -8.00 ppm, respectively. No resonances arising from boron-attached protons could be detected in either solvent.<sup>8</sup>

**Deuterium Isotope Effect in Trimethylamine Borane-Iodine Reaction. 1. Competitive Reactions.** Normal and deuterated (1.00 mmole of each) trimethylamine boranes in 5 ml of pyridine were mixed with 0.99 mmole of iodine; after 8 hr at room temperature (24°) the iodine color had disappeared. Following removal of the solvent below room temperature, the hexafluorophosphate salt was prepared as above but not recrystallized, and the deuterium content was determined by an infrared analysis of  $CH_2Cl_2$  solutions from the ratio of absorbancies at 2460 and 1890  $cm^{-1}$ .<sup>9</sup> In a second experiment, a similar mixture was heated for 3.5 hr at 90° prior to adding iodine to the cooled solution. The reaction in this instance was completed in less than 3.5 hr. The results are given in Table II and are compared with the results calculated from the rate constants.

after a second portion of iodine was injected.<sup>10</sup> The rate dependence on trimethylamine borane concentration agreed well with a first-order dependence on this component. The results are listed in Table III.

### Discussion

The formation of bis(pyridine)boronium ion from sodium borohydride occurs *via* a clear-cut reaction sequence involving hydride transfer from borohydride to iodine,<sup>11</sup> trapping of the BH<sub>3</sub> group by the solvent base, and a second similar sequence involving the intermediate pyridine borane. Hydride transfer to the iodine species in pyridine results in iodide ion and pyridinium ion, which also produces pyridine borane in a side reaction with borohydride.<sup>12</sup> The processes can be represented by

The great difference in reactivity between BH<sub>4</sub><sup>-</sup> and pyBH<sub>3</sub> toward electrophilic attack by either iodine or pyH<sup>+</sup> makes it possible to observe a clean separation of the reaction steps. The data also imply that the borohydride-pyridinium reaction proceeds more rapidly than the pyridine borane-iodine reaction; otherwise, more than the observed stoichiometric ratio of iodine should have been used at the point where hydrogen evolution had stopped.

The foregoing suggests a somewhat similar sequence in the reaction of trimethylamine borane with iodine. But since in this reaction the bispyridine ion is obtained in high yield, the question arises as to which stage of the reaction the necessary displacement of trimethylamine occurs: before or after attack on the B-H bond by iodine.

In separate experiments it was verified that pyridine borane reacts with the halogen much more rapidly than trimethylamine borane.<sup>13</sup> Thus, the displacement

(10) In the initial reaction log *A* vs. *t* plots had a slight curvature; the slope of log (rate) vs. log *A* plots indicated an apparent initial order of 0.8.

(11) G. F. Feguard and L. H. Long, *Chem. Ind.* (London), 471 (1965), report a high yield of diborane from NaBH<sub>4</sub> and I<sub>2</sub> in diglyme.

would have to be rate determining if it occurred prior to reaction with iodine (eq 5)

The alternate path would produce N(CH<sub>3</sub>)<sub>3</sub>BH<sub>3</sub>I, N(CH<sub>3</sub>)<sub>3</sub>pyBH<sub>3</sub><sup>+</sup>, or pyBH<sub>3</sub>I as intermediates, and, finally, (py)<sub>2</sub>BH<sub>3</sub><sup>+</sup> (eq 6). In view of the results ob-

tained with trimethylamine chloroborane, the proposed iodoborane intermediates could hardly be expected to survive long without iodide solvolysis in the reaction medium, but one might expect the mixed boronium ion to be capable of isolation.<sup>14</sup> Nevertheless, it was not possible to isolate this material even from mixtures which were not heated. If this compound indeed appears as an intermediate, it is also solvolyzed rather rapidly.<sup>15</sup>

The experiments with the deuterated borane, however, do allow a distinction between paths 5 and 6. The rate-determining transamination should not be sensitive to deuterium substitution on boron, whereas a hydride transfer should exhibit a pronounced isotope effect.<sup>16</sup> Moreover, in eq 5 the rate of disappearance of iodine should be independent of iodine concentration, but path 6 would predict a simple rate dependence on iodine. The experimental results clearly show that the rate depends on the iodine concentration (first order) and that there is a large deuterium isotope effect ( $k_H/k_D = 2.0$ ). The directly determined rate constants lead to a calculated isotope distribution in the product from the competitive reactions in most satisfactory agreement with the observed distribution. It is therefore concluded that the initial reaction step is a hydride abstraction from trimethylamine borane and that this step is the rate-determining one.

The maximum value for the ratio  $k_H/k_D$  can be estimated from the B-H and B-D stretching vibrations under the assumption that the rate constants differ primarily because of different zero-point energies in the ground state which are lost on stretching the bonds in the transition state. The ratio calculated from the experimental frequencies for trimethylamine borane is 4.4 at 25°. One can interpret the substantially lower experimental value,  $k_H/k_D = 2.0$ , as being the consequence of incomplete loss of zero-point energy in the transition state, corresponding to the retention of some bonding between boron and hydrogen. Nevertheless, the present value constitutes the largest isotope effect for reactions on B-H bonds which have come to our attention.<sup>17,18</sup>

It now seems plausible to view the reaction with the mercury(II) complex as analogous to the above examples: hydride transfer from the borane to the mer-

cury atom, followed by decomposition of the complex into atomic mercury, the ligands, and a proton. The question whether the mercury-attached ligand can transfer simultaneously to the boron atom, or whether it leaves the reaction sphere, at present remains un-

resolved, but we hope to contribute in the future to the solution of this problem.

## Spectra and Structure of Some Transition Metal Poly(1-pyrazolyl)borates

J. P. Jesson, S. Trofimenko, and D. R. Eaton

*Contribution No. 1265 from the Central Research Department, Experimental Station, E. I. du Pont de Nemours and Company, Wilmington, Delaware 19898.*

*Received December 7, 1966*

**Abstract:** Spectral and magnetic data are presented for a new family of transition metal chelates involving poly(1-pyrazolyl)borate ligands. These molecules behave as univalent ligands which can be either bidentate or tridentate depending on the number of pyrazolyl groups. Neutral complexes with the ions  $Mn^{2+}$ ,  $Fe^{2+}$ ,  $Co^{2+}$ ,  $Ni^{2+}$ ,  $Cu^{2+}$ , and  $Zn^{2+}$  have been studied. The bidentate  $Ni^{2+}$  and  $Cu^{2+}$  complexes are essentially planar. Other complexes with bidentate ligands are tetrahedral. The tridentate ligands give rise to octahedral complexes. Thus the poly(1-pyrazolyl)borate ligands provide an opportunity for physical studies of a range of complexes with different geometries and different metal ions but with essentially constant ligand characteristics. The results of such a study are reported.

In another publication<sup>1</sup> the synthesis and properties of a number of poly(1-pyrazolyl)borate transition metal complexes have been reported briefly. The series of complexes with divalent transition metal ions is of particular interest in that these ligands offer the opportunity of forming chelates of the same metal ion with different geometries. In the present paper, nuclear magnetic resonance, magnetic susceptibility, and electronic spectral data are described for complexes with the ions  $Mn^{2+}$ ,  $Fe^{2+}$ ,  $Co^{2+}$ ,  $Ni^{2+}$ ,  $Cu^{2+}$ , and  $Zn^{2+}$ . Both bidentate and tridentate ligands are involved, and the physical evidence presented suffices to characterize the geometries of the complexes. In the following paper the spin equilibria found with the  $Fe^{2+}$  complexes will be discussed in more detail.<sup>2</sup>

The complexes fall into two general classes. It is shown that in the first of these the bis(1-pyrazolyl)borate unit behaves as a bidentate chelating ligand and that the resulting compounds have structures of type

I

I, where R is H, alkyl, or aryl, and the pyrazolyl residues may contain substituents. We adopt the convenient abbreviation  $M[R_2B(pz)_2]_2$  and will indicate specifically when substituted pyrazolyl groups are involved. These complexes may have either an essentially planar configuration about the metal ( $Ni^{2+}$ ,  $Cu^{2+}$ ) or an essentially tetrahedral array ( $Mn^{2+}$ ,  $Fe^{2+}$ ,  $Co^{2+}$ ,  $Zn^{2+}$ ).

In the second class, tridentate ligands are involved as exemplified by structure II, and this structure occurs

II

with all six metals. We adopt the abbreviation  $M[R_2B(pz)_3]_2$ . R may be an alkyl or aryl group or another 1-pyrazolyl residue. Here we are dealing with a basically octahedral array of nitrogen atoms about the metal. Molecular models indicate that these tridentate complexes can be formed without strain, and the resulting molecule is highly symmetrical and compact. When R, X, and Y are hydrogen, molecules of type II have a structure belonging to the  $D_{3d}$  point group, and a predominantly octahedral ligand field is expected with a pronounced trigonal component. The evidence on

which the individual complexes are assigned their various structures will be considered in the light of magnetic and spectral data.

The optical data have been analyzed in terms of the crystal-field theory, and consideration is given to the position of the ligands in the spectrochemical and nephelauxetic series.

Epr studies of the Co<sup>2+</sup> compounds have also been made and have been reported elsewhere.<sup>3</sup> The evidence for the structures postulated above will first be summarized and the various physical measurements then discussed in detail.

### Summary of Evidence for Geometric Structures

The assignment of octahedral geometry to complexes of the form  $M[HB(pz)_3]_2$  and  $M[B(pz)_4]_2$  is based on the following observations.

1. All the complexes  $M[HB(pz)_3]_2$  have been shown to be isomorphous. They are stable, well-characterized compounds with analyses and molecular weights corresponding closely to the formulas given.

2. The room-temperature effective magnetic moments of the pairs  $M[HB(pz)_3]_2$ ,  $M[B(pz)_4]_2$  are closely similar and consistent with those found for octahedral coordination in the literature.

3. The electronic spectra of the pairs  $M[HB(pz)_3]_2$ ,  $M[B(pz)_4]_2$  are closely similar and agree well with other octahedral spectra in the literature.

4. The diamagnetism of  $Fe[B(pz)_4]_2$  gives strong evidence for octahedral coordination. Low-spin ferrous complexes are relatively common, the six d electrons filling the  $t_{2g}$  orbitals to give a  $^1A_{1g}$  ground state.

5. Proton nuclear resonance for the Co complexes shows that the six pyrazolyl residues in  $Co[HB(pz)_3]_2$  are equivalent, and the additional two in  $Co[B(pz)_4]_2$  are different. The resonances of the six equivalent pyrazole residues are in approximately the same positions for the two complexes.

6. Single crystal epr data for the Co<sup>2+</sup> complexes can only be interpreted in terms of an axially distorted octahedral crystal field about the cobalt atom.<sup>3</sup> The magnetically dilute powder epr spectra of  $Co[HB(pz)_3]_2$  and  $Co[B(pz)_4]_2$  are very similar.

7. The fact that the tris- and tetrakis(1-pyrazolyl)-borate ions are tridentate, uninegative ligands provides a ready explanation of their inability to form neutral chelates with trivalent metal ions of the type usually found for bidentate ligands. Thus iron(III) reacts with  $B(pz)_4^-$  forming the complex ion  $Fe[B(pz)_4]_2^+$  isolable as the nitrate or hexafluorophosphate.<sup>4</sup>

Turning to the remaining compounds, molecular models indicate that  $[H_2B(pz)_3]^-$  can act only as a bi-

dentate ligand, and the complexes of the form  $M[H_2B(pz)_3]_2$  give molecular weights and analyses corresponding closely to this formula. They are therefore four-coordinate and either tetrahedral or planar. The evidence on which decisions have been made between the alternatives is summarized below.

$Ni[H_2B(pz)_3]_2$ . The diamagnetism of this compound is strong evidence for its planar structure. This is supported by the electronic spectral data, the longest wave transition being at 21,000 cm<sup>-1</sup>. Tetrahedral Ni<sup>2+</sup> complexes, which cannot be diamagnetic within the framework of simple ligand-field theory, show absorption at much longer wavelengths.

$Cu[H_2B(pz)_3]_2$ . This compound is isomorphous with the Ni complex. The d-d transition observed in the electronic spectrum is at too high a frequency to be from a tetrahedral system. Using the electrostatic -4/9 ratio for the splitting due to a tetrahedral field relative to an octahedral field and comparing with the octahedral  $\Delta$  value, a tetrahedral copper dihydrobis-(1-pyrazolyl)borate would be expected to absorb at about 7000 cm<sup>-1</sup>. If Jahn-Teller effects are important in the octahedral case, the predicted tetrahedral absorption would be at even longer wavelengths. The longest wavelength absorption in  $Cu[H_2B(pz)_3]_2$  is at 18,500 cm<sup>-1</sup>.

$Co[H_2B(pz)_3]_2$  and  $Zn[H_2B(pz)_3]_2$ . The proton nmr spectra show all four pyrazolyl residues to be equivalent with the shifts of the cobalt compound being quite different from those for the octahedral complexes. The effective magnetic moment is in the middle of the range for the tetrahedral Co(II). High-spin planar Co(II) cannot be ruled out on the basis of magnetic data, but the complex is isomorphous with  $Zn[H_2B(pz)_3]_2$  and not with  $Cu[H_2B(pz)_3]_2$  and  $Ni[H_2B(pz)_3]_2$ . The optical data give strong support to the assignment. All three spin-allowed transitions have been detected, and the splittings and intensities are similar to those for other tetrahedral Co(II) systems in the literature. Four-coordinate Zn(II) complexes are always tetrahedral unless steric requirements make this impossible (e.g., zinc phthalocyanine).

$Fe[H_2B(pz)_3]_2$  and  $Mn[H_2B(pz)_3]_2$ . Optical data for the Fe(II) complex give strong evidence for tetrahedral coordination.  $\Delta$  for the high-spin octahedral ferrous complexes studied is ~12,500 cm<sup>-1</sup>,<sup>2</sup> and so a  $\Delta$  of ~6000 cm<sup>-1</sup> would be expected for high-spin tetrahedral coordination. Absorption corresponding to the  $^5T_2 \leftarrow ^5E$  transition (separation  $\Delta$ ) is found at 5800 cm<sup>-1</sup>. The magnetic moments are consistent with the tetrahedral assignment, but high-spin planar structures could not be ruled out on this basis. The change in the sign of the B<sup>11</sup> nmr shift on passing from  $Mn[B(pz)_4]_2$  (+1692 cps) and  $Mn[HB(pz)_3]_2$  (+1882 cps) to  $Mn[H_2B(pz)_3]_2$  (-2593 cps) must in any mechanism indicate a change in geometry.

**A. Susceptibility Data.** The effective magnetic moments of the complexes measured in solution at room temperature and calculated assuming the Curie law is obeyed are given in Table I. Satisfactory measurements of the moments for  $\text{Mn}[\text{H}_2\text{B}(\text{pz})_2]_2$  and  $\text{Fe}[\text{H}_2\text{B}(\text{pz})_2]_2$  could not be obtained because of the instability of the complexes.  $\text{Fe}^{2+}$  and  $\text{Mn}^{2+}$  complexes of structure I ( $\text{X} = \text{CH}_3$ ,  $\text{Y} = \text{H}$ ) are more stable, and room-temperature moments for these compounds are included in the table. We shall consider the magnetic data for each metal in turn, indicating how the information supports the molecular structures which have been assigned to the compounds. It should be emphasized that the moments given are to be viewed as qualitative indicators of the gross molecular structure. The influence of low-symmetry components of the field, corrections for temperature-independent paramagnetism, and possible non-Curie law behavior have been ignored.

**$\text{Mn}^{2+}$ .** High-spin  $\text{Mn}^{2+}$  has a  ${}^6\text{A}_1$  ground state in both octahedral and tetrahedral coordination. This is the only spin sextet of the configuration, and departures from the spin-only value of the moment (5.92) due to spin-orbit mixing of higher states and low symmetry components of the crystal field are expected to be small. The measured moments are consistent with the assignment of a tetrahedral structure to  $\text{Mn}[\text{H}_2\text{B}(\text{pz})_2]_2$  and an octahedral structure to  $\text{Mn}[\text{HB}(\text{pz})_2]_2$  and  $\text{Mn}[\text{B}(\text{pz})_4]_2$ . Tetrahedral and octahedral  $\text{Mn}^{2+}$  cannot, of course, be distinguished on the basis of their magnetic moments.

**$\text{Fe}^{2+}$ .** High-spin octahedral  $\text{Fe}^{2+}$  has a  ${}^5\text{T}_{2g}$  ground state and gives room-temperature moments of about 5.3 BM, which are relatively insensitive to temperature. High-spin tetrahedral  $\text{Fe}^{2+}$  has a  ${}^5\text{E}$  ground state with moments in the 5.1-BM range. A distinction between the two types of coordination for high-spin cases on the basis of their moments is of dubious validity since low-symmetry components of the field can produce appreciable variations in the effective moment.

A clear distinction between tetrahedral and octahedral geometries is possible for low-spin  $\text{Fe}^{2+}$  since the octahedral low-spin ground state is  ${}^1\text{A}_{1g}$ , the  $t_{2g}$  orbitals being completely occupied, and complexes of this type are, of course, diamagnetic. The low-spin tetrahedral ground state would be  ${}^3\text{T}_1$ . The diamagnetism of  $\text{Fe}[\text{B}(\text{pz})_4]_2$  is then clear evidence for essentially octahedral coordination. Additional evidence is provided by the singlet-quintet spin equilibrium shown by  $\text{Fe}[\text{HB}(\text{pz})_2]_2$  and discussed elsewhere.<sup>2</sup> Octahedral  $\text{Fe}^{2+}$  is one of the most likely situations for the observation of a spin-free-spin-paired equilibrium, the required mean pairing energy being in the region of 15,000  $\text{cm}^{-1}$  and varying according to the degree of reduction of the interelectronic repulsion integrals by covalent bonding of the ligand. Complex II ( $\text{X} = \text{Y} = \text{CH}_3$ ) is completely high spin with a room-temperature moment of 5.22 BM. The moment of 5.2 BM for complex I ( $\text{X} = \text{CH}_3$ ,  $\text{Y} = \text{H}$ ) is consistent with the assignment of tetrahedral geometry.

**$\text{Co}^{2+}$ .** Tetrahedral  $\text{Co}^{2+}$  has a  ${}^4\text{A}_2$  ground state with a moment given approximately by

$$\mu_{\text{obsd}} = 3.87 \left( 1 + \frac{4\zeta}{3\Delta} \right)$$

where  $\Delta$  is the one-electron crystal-field parameter, and

$\zeta$  is the single-electron spin-orbit parameter. Because of the possibility of relatively large percentage changes in  $\Delta$  ( $\Delta$  for tetrahedral  $\text{Co}^{2+}$  being in the region 3000  $\text{cm}^{-1}$ ) and the large spin-orbit parameter ( $\zeta = 540 \text{ cm}^{-1}$ ),  $\mu_{\text{obsd}}$  can cover a quite wide range. Values have been found from  $\sim 4.2$  to  $\sim 4.9$  BM. The upper end of this range overlaps values found for octahedral coordination (4.7–5.4 BM), and the assignment of geometry on the basis of room-temperature moment is not always possible. The fact that  $\text{Co}[\text{H}_2\text{B}(\text{pz})_2]_2$  is isomorphous with  $\text{Zn}[\text{H}_2\text{B}(\text{pz})_2]_2$  argues strongly for tetrahedral coordination, and the moment of 4.52 BM places it right in the middle of the tetrahedral range.

The high-spin ground state in octahedral coordination is  ${}^4\text{T}_{1g}$ , and an appreciable temperature dependence of the moment is anticipated. Distortions in the octahedral field can give rise to large anisotropy in the magnetic moment and  $g$ -tensor components which would not be found for tetrahedral coordination. Magnetically dilute single-crystal epr measurements in  $\text{Co}[\text{HB}(\text{pz})_2]_2$  at 4.2°K give unambiguous evidence for an axially distorted octahedral field.<sup>3</sup> The magnetically dilute powder epr of  $\text{Co}[\text{HB}(\text{pz})_2]_2$  and  $\text{Co}[\text{B}(\text{pz})_4]_2$  are very similar, indicating the same geometry about  $\text{Co}^{2+}$ . The room-temperature moments of 5.40 and 5.24 BM for  $\text{Co}[\text{HB}(\text{pz})_2]_2$  and  $\text{Co}[\text{B}(\text{pz})_4]_2$  are good for octahedral coordination.

**$\text{Ni}^{2+}$ .** The zero magnetic moment for  $\text{Ni}[\text{H}_2\text{B}(\text{pz})_2]_2$  provides unambiguous evidence for essentially square-planar  $\text{Ni}^{2+}$ . The electrons are paired owing to the strong antibonding character of the  $d$  orbital involved in  $\sigma$  bonding to the square-planar array ( $d_{x^2-y^2}$ , for a coordinate system in which the  $x$  and  $y$  axes pass through the nitrogen atoms).  $\text{Ni}[\text{H}_2\text{B}(\text{pz})_2]_2$  is isomorphous with  $\text{Cu}[\text{H}_2\text{B}(\text{pz})_2]_2$  which must also be planar. Octahedral  $\text{Ni}^{2+}$  gives rise to a  ${}^3\text{A}_{2g}$  ground state. The moment is given approximately by

$$\mu_{\text{eff}} = 2.83 \left( 1 + \frac{2\zeta}{\Delta} \right)$$

and should be relatively insensitive to temperature and small departures from octahedral symmetry. Values of 2.9–3.3 BM have been found. Using the free ion value of  $\zeta = 650 \text{ cm}^{-1}$ , we would have  $\Delta = 9400 \text{ cm}^{-1}$ . This value is in poor agreement with the value of  $\Delta = 12,000 \text{ cm}^{-1}$  found from the optical data. The discrepancy is perhaps not surprising in view of the approximations involved in the formula for the effective moment, and the value of 12,000  $\text{cm}^{-1}$  is probably closer to the true value. The room-temperature moments of 3.22 and 3.24 BM for  $\text{Ni}[\text{HB}(\text{pz})_2]_2$  and  $\text{Ni}[\text{B}(\text{pz})_4]_2$  are consistent with the postulated octahedral geometry.

**$\text{Cu}^{2+}$ .** The ground state for octahedral copper,  ${}^2\text{E}_g$ , consists of two noninteracting Kramer's doublets, and the moment is relatively insensitive to distortions. Similar moments are therefore found for planar and octahedral environments. Values of  $\sim 1.9$  BM are usually obtained. The measurements on the Cu complexes are less accurate than those for the other metals because of the small nmr shifts involved. Jahn-Teller distortions can be important in these systems.

**B. Optical Data.** In considering the optical data, it is convenient to discuss the molecules of a given

geometry collectively. After a brief consideration of the zinc complexes, first the planar, then the tetrahedral, and finally the octahedral complexes will be discussed.

**1. Zinc Complexes.** The transitions in these complexes are probably intraligand in character and set a short wavelength limit for the absorptions in the other complexes which may be assigned to the d-d and charge-transfer transitions involving the metal. The data for the three zinc complexes measured in cyclohexane solution are given in Table II. The possibility

**Table II.** Ultraviolet Absorption Spectra of Zinc Complexes Measured in Cyclohexane Solution

Compound	$\lambda$ , $m\mu$	$\nu$ , $\text{cm}^{-1}$	$\epsilon$	Comment	Assignment
$\text{Zn}[\text{H}_2\text{B}(\text{pz})_2]_2$	218	45,900	24,000	Shoulder	Intraligand
	215	46,500	23,000		
$\text{Zn}[\text{HB}(\text{pz})_2]_2$	216	46,300	17,000	Shoulder	Intraligand
	210	47,600	33,000		
	205	48,800	34,000

	212	47,200	30,000		
	207	48,300	31,000		

that some of the transitions are metal-to-ligand charge transfer is, of course, not completely ruled out, but the wavelengths observed are reasonable for aromatic  $\pi^* \leftarrow \pi$  absorption.

**2. Planar Complexes.** There can be little doubt that there is an essentially planar array of nitrogen atoms about the metal in these complexes. It does not follow, however, that the pyrazole rings and boron atoms, as shown in structure I, are also coplanar. In fact, molecular models indicate that the borons are probably out of the plane of the rings and that the rings may be inclined to one another. Two forms of the molecule  $\text{M}[\text{H}_2\text{B}(\text{pz})_2]_2$  could then exist: a "boat" form with both borons up and a "chair" form with one up and one down. With chelates of structure I ( $\text{X} = \text{CH}_3$ ,  $\text{Y} = \text{H}$  or any other group), only the chair form is possible for steric reasons. The molecular symmetry is therefore less than  $D_{4h}$ . However, in the present discussion it will be assumed that only nearest neighbors to the metal need be considered and that the local symmetry is  $D_{4h}$ .

The molecular orbital theory of this type of complex has been considered by Gray and Ballhausen<sup>5</sup> and by Liehr, *et al.*<sup>6</sup> A complete ligand-field calculation, including spin-orbit effects, has been made by Fenske, *et al.*,<sup>7</sup> for  $\text{Pt}^{2+}$ . They find the orbital ordering  $d_{xz}, d_{yz} < d_{xy} < d_{z^2} < d_{x^2-y^2}$ . The  $x$  and  $y$  axes pass through the ligand atoms at the corners of a square array. Some confidence may be placed in this ordering for  $\text{Pt}^{2+}$ , but it could be different when other metals are considered. Gray and Ballhausen<sup>5</sup> suggest that the lowest unoccupied orbital which is mainly ligand in character,

for systems where the ligand has a  $\pi$  system, will be  $a_{2u}(\pi^*)$  and that the long-wavelength charge-transfer transitions in their  $d^8$  complexes involve transfer of an electron from the metal to this orbital. The data and assignments for the two planar pyrazole complexes are given in Table III.

<sup>a</sup> In cyclohexane solution. Others in dichloromethane.

$\text{Ni}[\text{H}_2\text{B}(\text{pz})_2]_2$ . The first band, in view of its extinction coefficient, must be assigned to the first d-d transition  $(d_{x^2-y^2})(d_{xy}) \leftarrow (d_{xy})^2$ . It is somewhat stronger than the corresponding transition in the compounds studied by Gray and Ballhausen. The band is quite symmetrical, and a search to longer wavelengths with more concentrated solutions did not reveal any further absorption (such as the associated singlet-triplet transition). The first charge-transfer transition,  $^1B_{1u} \leftarrow ^1A_{1g}$ , is orbitally forbidden and is assigned to the absorption at 277  $m\mu$  which has the reasonable extinction coefficient  $\epsilon$  1400. The next two charge-transfer transitions are orbitally allowed, and the transition to the  $^1E_u$  state was found by Gray and Ballhausen to be the stronger of the two. The assignments in Table III have been completed on this basis. It is possible there is some splitting of the  $E_u$  state due to departures from  $D_{4h}$  symmetry. Neglecting exchange and Coulomb integrals between electrons centered on different atoms and evaluating those for electrons on the same atom in terms of the Slater-Condon theory for complex atoms, Gray and Ballhausen<sup>5</sup> found the following energies for the optical transitions.

$$^1A_{2g} \leftarrow ^1A_{1g} \quad \Delta_1 - 35F_4$$

$$^1B_{1u} \leftarrow ^1A_{1g} \quad \Delta E(^1B_{1u})$$

$$^1A_{2u} \leftarrow ^1A_{1g} \quad \Delta E(^1B_{1u}) + \Delta_2 - 20F_2 + 100F_4$$

$$^1E_u \leftarrow ^1A_{1g} \quad \Delta E(^1B_{1u}) + \Delta_2 + \Delta_3 - 15F_2 + 75F_4$$

where  $\Delta_1$ ,  $\Delta_2$ , and  $\Delta_3$  are the one-electron splittings  $(x^2 - y^2) - (xy)$ ,  $(xy) - (z^2)$ ,  $(z^2) - (xz, yz)$ ;  $\Delta E(^1B_{1u})$  is the energy of the  $^1B_{1u} \leftarrow ^1A_{1g}$  transition; and  $F_2$  and  $F_4$  are the Slater-Condon interelectronic repulsion integrals.

Using  $F_2 = 10F_4 = 700 \text{ cm}^{-1}$ , the assignments in Table III lead to  $\Delta_1 = 23,700 \text{ cm}^{-1}$ ;  $\Delta E(^1B_{1u}) = 36,100 \text{ cm}^{-1}$ ;  $\Delta_2 = 11,400 \text{ cm}^{-1}$ ; and  $\Delta_3 \approx 0$ .

<sup>a</sup> Measured in cyclohexane.

As expected,  $\Delta_1$  is by far the largest of the  $\Delta$  values due to the strongly antibonding character of the  $\sigma$ -bonding  $d_{z^2-y^2}$  orbital. The value of  $\Delta_1$  is close to that found in Ni(CN)<sub>4</sub><sup>2-</sup>, and the  $\Delta_2$  and  $\Delta_3$  values are also quite similar. As with most calculations of this type, the results are quite sensitive to the values of  $F_2$  and  $F_4$  chosen (we have used the values selected by Gray and Ballhausen), and so the final parameters, particularly  $\Delta_2$  and  $\Delta_3$ , are subject to fairly large errors. From the comparison of spectra in planar d<sup>8</sup> complexes in cases where the ligand has no  $\pi$  system with those cases where a  $\pi$  system is present, Gray and Ballhausen were able to establish a pattern for ligand-to-metal and metal-to-ligand charge transfer. They concluded that ligand-to-metal transitions would be separated by  $\sim 10,000$  cm $^{-1}$ , while the metal-to-ligand transitions are separated by only 2000–3000 cm $^{-1}$ . The assignments made here are consistent with this scheme.

Cu(H<sub>2</sub>B(pz)<sub>2</sub>)<sub>2</sub>. The assignments in Table III for the copper complex have been made in the same way. The d-d transition  $(x^2 - y^2)(xy) \leftarrow (x^2 - y^2)(xy)^2$  is of similar intensity to the corresponding transition in the nickel complex, and again it must be assumed that the remaining d-d transitions are obscured by charge-transfer absorption. For copper, again assuming charge transfer to the low-lying  $a_{2u}(\pi^*)$  orbital, the first two charge-transfer transitions are forbidden. The assigned transitions have similar intensity to the forbidden charge-transfer transition in the nickel example. It would be dangerous to assign the absorptions at 219 and 203 m $\mu$  to particular metal-to-ligand transitions since they may be intraligand in character. The energy of the d-d transition  $(b_{1g})(b_{2g}) \leftarrow (b_{1g})(b_{2g})^2$  is  $\Delta_1$ . Denoting the energy of the first charge-transfer transition as  $\Delta E(^2A_{2u})$ , an estimate of the interelectronic repulsion correction for the  $A_{1u}$  transition is required. The configuration  $(b_{2g})(b_{1g})(a_{2u})\dots$  gives rise to two doublet states and a quartet. The important doublet for our purposes may be written in the form

$$(^1/2)^{1/2} [ \dots (xy)(\bar{a}_{2u})(x^2 - y^2) | - \\ | \dots (\bar{xy})(a_{2u})(x^2 - y^2) ] ]$$

Using the approximation of neglecting repulsion integrals between ao's on different centers, the energy

of the  $^2A_{1g}$  transition is

$$\Delta E(^2A_{2u}) = \Delta_1 - 175F_4/2$$

The final parameters for the copper complex are therefore  $\Delta_1 = 18,450$  and  $\Delta E(^2A_{2u}) = 30,500$ .

The expression for  $\Delta E(^2A_{1u})$  would require  $F_4 \sim 20$  cm $^{-1}$ . In view of the approximations involved, this result cannot be viewed as a determination of  $F_4$ , and the true value is almost certainly larger.  $\Delta_1$  appears to be significantly lower for Cu than for Ni.

The spectra described above provide strong support for the structures assigned on the basis of the magnetic data and rule out the possibility of tetrahedral coordination in either of the complexes.

3. Tetrahedral Complexes, M(H<sub>2</sub>B(pz)<sub>2</sub>)<sub>2</sub> (M = Zn<sup>2+</sup>, Co<sup>2+</sup>, Fe<sup>2+</sup>, Mn<sup>2+</sup>). Data for the Zn<sup>2+</sup> complex have been presented in Table II. The Fe<sup>2+</sup> and Mn<sup>2+</sup> complexes derived from dihydrobis(3,5-dimethyl-1-pyrazolyl)borate were used in the study because of their enhanced stability over the unsubstituted compounds. No d-d transitions were observed for the Mn<sup>2+</sup> complex for the path lengths and concentrations available. Data for the remaining two complexes are given in Table IV.

Co(H<sub>2</sub>B(pz)<sub>2</sub>)<sub>2</sub>. There are many optical studies of tetrahedral Co(II) complexes in the literature. The most detailed work has been carried out by Ferguson<sup>8</sup> using low-temperature and polarized-single-crystal techniques. Cotton<sup>9</sup> has studied a variety of tetrahedral Co(II) compounds both in solution and as mulls. In these studies it has been assumed that the first spin-allowed transition  $^4T_1 \leftarrow ^4A_2$  lies in the 3- $\mu$  region, outside the spectral range covered, giving a  $\Delta$  of 3000–4000 cm $^{-1}$ . Transitions to the  $^4T_1(^4F)$  and  $^4T_1(^4P)$  states then lie at  $\sim 5500$  and  $\sim 15,000$  cm $^{-1}$ . Because of the absence of a center of symmetry and consequent mixing of d and p orbitals in these systems, the d-d transitions are commonly 100–200 times more intense than for octahedral coordination. In the present case, the transition in the 3- $\mu$  region has been observed by comparing the infrared spectra of Zn(H<sub>2</sub>B(pz)<sub>2</sub>)<sub>2</sub> and Co(H<sub>2</sub>B(pz)<sub>2</sub>)<sub>2</sub> in CCl<sub>4</sub> solution at the same concentration.

spectra are shown in Figure 1. The sharp vibrational structure and  $\text{CCl}_4$  absorption (there was no ncing solvent cell) are quite similar in the two cases, there is an underlying broad absorption in the  $\text{Co(II)}$  pound due to the  ${}^4\text{T}_2 \leftarrow {}^4\text{A}_1$  transition.

Figure 1. Absorption spectra ( $3\ \mu$ ) of  $\text{Zn}[\text{H}_3\text{B}(\text{pz})_2]_2$  and  $\text{Co}[\text{H}_3\text{B}(\text{pz})_2]_2$  in  $\text{CCl}_4$ .

The spectrum in the 17,000–3500-Å region is shown in Figure 2. Large splittings are observed in the  $\text{F} \leftarrow {}^4\text{A}_2$  and  ${}^4\text{T}_1(\text{P}) \leftarrow {}^4\text{A}_2$  transitions and are attributed to the effect of spin-orbit coupling and low-symmetry components in the crystal field. Jahn-Teller distortions in the excited states are theoretically possible, they are probably small in view of the large spin-orbit contribution. Three well-resolved maxima are found for the  ${}^4\text{T}_1(\text{P})$  transition. The  ${}^4\text{T}_1$  components are probably quite strongly mixed with components of the  ${}^2\text{G}$  state which occur in the same region, and the splitting observed is quite characteristic of  $\text{Co}^{2+}$  in tetrahedral coordination.<sup>10-13</sup> The two bidentate ligand residues in  $\text{Co}[\text{H}_3\text{B}(\text{pz})_2]_2$  would be expected to give rise to a low-symmetry component in the crystal field of approximately  $\text{D}_{2d}$  symmetry. It is possible that the well-resolved doublet structure in the transition to the  ${}^4\text{T}_1(\text{F})$  state can be accounted for as the splitting  ${}^4\text{T}_1 \leftarrow {}^4\text{A}_2 + \text{E}$ .

Since the  ${}^4\text{T}_2 \leftarrow {}^4\text{A}_2$  transition should occur at a frequency  $\Delta\ \text{cm}^{-1}$ , the infrared measurement indicates  $\Delta = 3200\ \text{cm}^{-1}$ . However, the transition  ${}^4\text{T}_1(\text{F}) \leftarrow {}^4\text{A}_2$  should lie at approximately  $1.8\Delta$ , and based on this argument a value of  $\Delta \sim 4800\ \text{cm}^{-1}$  is obtained. A possible explanation of this discrepancy is that, in view of the intrinsic weakness of the transition to the  ${}^4\text{T}_2$  level, only the transition to the E component is observed, the  $\text{B}_2$  component being forbidden. The measured magnetic moment corresponds to a  $\zeta/\Delta$  value of approximately 0.13. Combination of this value with the known free ion spin-orbit coupling constant gives  $\Delta \sim 4100\ \text{cm}^{-1}$ . A further 10% reduction in  $\zeta$  due to covalency effects would give  $\Delta \sim 3700\ \text{cm}^{-1}$ . It does not, therefore, seem possible to choose between the

alternate  $\Delta$  values on the basis of the magnetic data. Just as for the planar complexes, it is probable that the boron atoms lie out of the plane of the pyrazole rings, and the rings may be inclined to one another. Two optically isomeric forms of the molecule would be possible, provided there is no rapid N-B-N inversion.

Figure 2. Absorption spectrum of  $\text{Co}[\text{H}_3\text{B}(\text{pz})_2]_2$ , 3500–17,000 Å, measured in  $\text{CHCl}_3$  solution.

$\text{Fe}[\text{H}_3\text{B}(\text{pz})_2]_2$ . The tetrahedral ferrous complexes are very easily oxidized in solution. Studies were made with the more stable chelate derived from dihydrobis(3,5-dimethyl-1-pyrazolyl)borate. A single band corresponding to the expected  ${}^6\text{T}_2 \leftarrow {}^6\text{E}$  transition is found at  $5800\ \text{cm}^{-1}$ . The separation of these energy levels is  $\Delta$  on the crystal-field model, and  $\Delta = 5800\ \text{cm}^{-1}$  is very close to  $1/3$  the  $\Delta$  for the octahedral systems ( $\sim 12,500\ \text{cm}^{-1}$ ).<sup>2</sup>

Tetrahedral  $\text{Fe}^{2+}$  complexes reported in the literature have no d-d absorption between 500 and 2000 m $\mu$ .<sup>14,15</sup> It seems unlikely that the  ${}^6\text{T}_2 \leftarrow {}^6\text{E}$  transition would be too weak to be observed, and probably  $\Delta$  is less than  $5000\ \text{cm}^{-1}$  for these systems.

**4. Octahedral Complexes,  $\text{M}[\text{HB}(\text{pz})_2]_2$  and  $\text{M}[\text{B}(\text{pz})_4]_2$**  ( $\text{M} = \text{Zn}^{2+}, \text{Cu}^{2+}, \text{Ni}^{2+}, \text{Co}^{2+}, \text{Mn}^{2+}$ ). The optical spectra of complexes  $\text{M}[\text{HB}(\text{pz})_2]_2$  and  $\text{M}[\text{B}(\text{pz})_4]_2$  are almost identical except for the ferrous compounds where a spin equilibrium is present in the first compound. The two types of complex will therefore be considered together. Results have already been given for the Zn complexes (Table II), and the absorption in the octahedral  $\text{Mn}^{2+}$  complexes was too weak to be detected in the effective concentrations available. Results for a variety of  $\text{Fe(II)}$  complexes are given in the following paper.<sup>3</sup> The results for the remaining complexes are given in Table V.

**$\text{Cu}[\text{HB}(\text{pz})_2]_2$  and  $\text{Cu}[\text{B}(\text{pz})_4]_2$ .** Both complexes give one very broad transition in the  $16,500\text{-cm}^{-1}$  region which may be assigned to the expected  ${}^3\text{T}_{2g} \leftarrow {}^3\text{E}_g$  transition. In both cases extended and very pronounced long-wavelength shoulders are found. There is some evidence of structure in the main absorption. Splittings are expected owing to the trigonal component of the field, spin-orbit coupling, and possible Jahn-Teller distortions. The apparent octahedral splitting parameter  $\Delta$ , neglecting Jahn-Teller effects, is  $\sim 16,000\ \text{cm}^{-1}$ , indicating a relatively strong ligand field. There is an increase by a factor of 3 in extinction

<sup>a</sup> Measured in cyclohexane solution.

coefficient with the substitution of the fourth pyrazole residue which is perhaps a little surprising. In the corresponding nickel and cobalt complexes there is essentially no change in extinction coefficient on substitution.

Ni[HB(pz)<sub>3</sub>]<sub>2</sub> and Ni[B(pz)<sub>3</sub>]<sub>2</sub>. Calculations have been made for these complexes using the "complete" ligand-field matrices of Liehr and Ballhausen<sup>16</sup> for Ni<sup>2+</sup> in an octahedral environment. The results must be viewed with some caution since it is probable there is a pronounced trigonal component in the crystal field. The calculated energy scheme as a function of  $\Delta$  is shown in Figure 3.  $\lambda$  has been taken as  $-285$  cm $^{-1}$  and  $F_4$  as  $90$  cm $^{-1}$ . The relation  $F_2 = 14F_4$  has been assumed. The measured transition frequencies for Ni[HB(pz)<sub>3</sub>]<sub>2</sub> are shown in the diagram as horizontal bars, and it is seen that there is good agreement with the calculated values for  $\Delta \approx 12,000$  cm $^{-1}$ . The transition frequencies of Ni[B(pz)<sub>3</sub>]<sub>2</sub> are very similar, and  $\Delta$  must also be close to  $12,000$  cm $^{-1}$  in this case. The assignments given in Table V are based on this calculation. Jørgensen<sup>17</sup> has suggested that, in Ni(H<sub>2</sub>O)<sub>6</sub><sup>2+</sup>,

the doubling of the absorption in the  $13,500$ -cm $^{-1}$  region is due to spin-orbit coupling between  ${}^3T_{1g}({}^3F)$  and  ${}^1E_g({}^1D)$ , giving rise to appreciable intensity for transitions to the latter state. The calculation of Liehr and Ballhausen<sup>16</sup> argues against this since the two states in question do not approach closely for the parameter values they have assumed. The energy scheme, however, depends quite sensitively on the values of  $F_2$  and  $F_4$  chosen, and the Jørgensen assignment cannot be completely ruled out. We have used the same  $F_2$  and  $F_4$  values as Liehr and Ballhausen, and, for the  $\Delta$  value established for polypyrazolylborates, the  ${}^1E$  state should be close to the  ${}^3T_{2g}$  state. This may account for the splitting of the absorption peak. [The spin-orbit splitting in the  ${}^3T_2$  state is much less than for  ${}^3T_1({}^3F)$ .]

Co[HB(pz)<sub>3</sub>]<sub>2</sub> and Co[B(pz)<sub>3</sub>]<sub>2</sub>. Most of the data for these compounds have been given in a publication describing paramagnetic resonance absorption in these systems.<sup>3</sup> Despite the large trigonal component in the crystal field indicated by the resonance data, there are no observable splittings of the orbital triplets in the optical spectrum. Koide<sup>18</sup> has shown that the transition to the  ${}^4A_{2g}$  state should be weak. It is a two-electron transition, and his theoretical oscillator strengths are in

Figure 3. Energy-level diagram for octahedral Ni(II) complexes as a function of  $\Delta$ . Measured Ni[HB(pz)<sub>2</sub>]<sub>2</sub> transitions shown as horizontal bars.

The zinc complexes are, of course, diamagnetic and show well-resolved spin-spin splittings. The resonance of the 4-H is a triplet (see structure I for numbering) and gives an unambiguous assignment. Assignments cannot be made for the 3- and 5-H with the data available. The resonances for the hydrogen on boron are very broad. Their centers have been established by integration. The line widths of nuclear resonance spectra in paramagnetic systems are determined by the effects of dipolar and scalar coupling of the nucleus with the unpaired electrons in the molecule.<sup>19</sup> Appreciable scalar coupling will often broaden the resonances beyond detectability unless the electron spin-lattice relaxation time is very short. For the ions involved in the present study, rapid spin-lattice relaxation is usually found for Co<sup>2+</sup> and Fe<sup>2+</sup> in octahedral coordination. (Liquid helium temperatures are usually required for the observation of paramagnetic resonance in these systems.) The Co<sup>2+</sup> and Fe<sup>2+</sup> complexes are the only octahedral poly(1-pyrazolyl)borates which give rise to well-resolved nmr spectra. The octahedral Ni<sup>2+</sup> complexes represent an intermediate case where some information can be obtained from the nmr (liquid nitrogen temperatures are usually needed to observe epr in these systems), and the Cu<sup>2+</sup> and Mn<sup>2+</sup> nmr spectra are too broad to provide useful information (epr can be observed at room temperature). Well-resolved proton resonance spectra are also found for the tetrahedral Fe<sup>2+</sup> and Co<sup>2+</sup> complexes. The tetrahedral Co<sup>2+</sup> ground state is orbitally nondegenerate, and the relaxation mechanism must involve coupling of the zero-field splitting to the lattice modes.

**Cobalt Complexes.** The Co<sup>2+</sup> complexes provide the most direct structural information since the spectra

M[B(pz) <sub>3</sub> ] <sub>2</sub>	+1690 <sup>a</sup>	+270	-3460 <sup>a</sup>	+940 <sup>a</sup>	+730	+260 <sup>a</sup>

<sup>a</sup> In CHCl<sub>3</sub> solution; others in CH<sub>2</sub>Cl<sub>2</sub>.

are not complicated by the presence of a spin equilibrium as is the case for Fe<sup>2+</sup>. The first three Co<sup>2+</sup> complexes in Table VI are octahedral and are sufficient to establish the assignments given. The assignments have been made on the basis of intensity, the effects of substitution, and from line widths and ease of saturation. In the limit of short electron spin-lattice relaxation times, the nuclear *T*<sub>2</sub> values and hence line widths are usually determined by dipolar terms which depend on the inverse of the sixth power of the distance of the proton from the electronic dipole, and so protons closest to the metal have the greatest half-widths. Direct evidence for the tridentate nature of the HB(pz)<sub>3</sub><sup>-</sup> and B(pz)<sub>3</sub><sup>-</sup> ligands is provided by comparison of the nmr spectra of Co[HB(pz)<sub>3</sub>]<sub>2</sub> and Co[B(pz)<sub>3</sub>]<sub>2</sub>. In the former complex the six pyrazolyl residues giving rise to three separate proton resonances are all equivalent. The proton resonance spectrum of Co[B(pz)<sub>3</sub>]<sub>2</sub> is shown in Figure 4. The addition of the fourth pyrazolyl resi-

Figure 4. Proton resonance spectrum of Co[B(pz)<sub>3</sub>]<sub>2</sub> in CDCl<sub>3</sub>. Shifts from TMS at 60 Mcps.

due gives rise to three new resonances of one-third the intensity of the main three resonances, and, of course, the resonance due to the proton on boron is no longer present. Assignments for the tetrahedral complexes Co[H<sub>2</sub>B(pz)<sub>2</sub>]<sub>2</sub> and I (M = Co, X = CH<sub>3</sub>, Y = H), given in Table VI, have been made in the same way.

The isotropic shifts in the octahedral compounds are determined predominantly by pseudo-contact interactions. A detailed analysis of these shifts together with complementary epr data will be published elsewhere.<sup>20</sup>

**Ni<sup>2+</sup> Complexes.** Results for the Ni<sup>2+</sup> complexes are given in Table VI. Ni[H<sub>2</sub>B(pz)<sub>2</sub>]<sub>2</sub>, which is diamagnetic, gives resonances in roughly the same positions as those of the zinc complexes or of the free ligand. In Ni[HB(pz)<sub>3</sub>]<sub>2</sub> only one resonance is observed due to the three ring protons. In Ni[B(pz)<sub>3</sub>]<sub>2</sub> the resonance for the ring protons splits into two components, and it

seems likely that the third resonance is also present in this grouping. The resonance due to H on boron is replaced by three resonances in essentially the positions for a free pyrazole residue, showing there is effectively no spin delocalization to this ring. Any appreciable dipolar shift is also ruled out. This is in harmony with the fact that the ground state is <sup>3</sup>A<sub>2</sub>, and the electronic moment would be expected to be isotropic.

**Boron Nuclear Resonances.** B<sup>11</sup> resonance shifts measured from trimethyl borate as an external standard at 14.2 Mcps are given in Table VII. Susceptibility corrections have been applied to the shifts. The Zn complexes provide diamagnetic reference points. For the M[HB(pz)<sub>3</sub>]<sub>2</sub> and M[B(pz)<sub>3</sub>]<sub>2</sub> complexes of the same metal the shifts are approximately the same except for the Fe<sup>2+</sup> case where the spin equilibrium is present. The shifts for the M[H<sub>2</sub>B(pz)<sub>2</sub>]<sub>2</sub> systems are in general quite different, the large low-field shifts in the Mn and Fe complexes providing additional evidence for the assumed geometrical differences.

## Discussion

The magnitude of Δ for a given metal ion determines the position of a ligand in the spectrochemical series. Jørgensen<sup>21</sup> has suggested that Δ may be represented as a product of two factors, one for the ligand and one for the central ion.

$$\Delta = f(\text{ligand}) \times g(\text{central ion})$$

The position of a ligand in the nephelauxetic series is determined by the reduction of the interelectronic repulsion integrals from the values in the free ion, the parameter β being defined by

$$B(\text{complex}) = \beta B(\text{free ion})$$

Again Jørgensen has suggested that this parameter may be split into a quantity characteristic of the ligand and one characteristic of the metal

$$1 - \beta = hk$$

where *h* refers to the ligand and *k* to the metal.

Values of Δ, *B*, and β for the complexes studied are given in Table VIII. *B* values for the free ion are given in parentheses. Values of the corresponding quantities for the hexaquo ions are given beneath the octahedral parameters for comparison. For the octahedral Ni(II) complexes the calculated transitions, using the undistorted octahedral model, are in very good agreement

(20) J. P. Jesson, to be published.

the experimental values (see Figure 3). All the  $t_2$  states are reproduced closely. The high-spin states for Co(II) are not reproduced so well. This is probably due to the effect of the trigonal component of the field perturbing the positions of the  ${}^4A_2$  and  ${}^4T_1(P)$  states which lie close together. In the Ni(II) all the high-spin states are well separated. In

O)	...	0.90	0.89	...		

<sup>a</sup>  $\Delta$  and  $B$  values in  $\text{cm}^{-1}$ .

estimating  $\Delta$  and  $B$  for the Ni(II) case, we have used the results of the ligand-field calculation which indicates 12,000  $\text{cm}^{-1}$  and the relationship

$$\delta(T_1) = (225B^2 - 18B\Delta + \Delta^2)^{1/2}$$

$\delta(T_1)$  is the separation between the two  $T_1$  states. The relevant parameters for establishing the position of the hydrotris(1-pyrazolyl)borate ligand in the spectrochemical and nephelauxetic series using the Ni(II) are then  $\Delta = 12,000 \text{ cm}^{-1}$  and  $\beta = 0.82$ . These lead to the final quantities  $f = 1.35$  and  $h = 1.5$ . The  $h$  value is quite sensitive to  $\delta(T_1)$ , and, because of the splittings of the  ${}^3T_2({}^3F)$  state,  $\delta(T_1)$  cannot be estimated accurately. The  $h$  value should therefore be accepted with some reservation. A value of  $\delta(T_1) = 10,000 \text{ cm}^{-1}$  has been used in the calculation. The  $B$  value is reasonably close to that assumed in the original crystal field level calculation ( $F_2 = 14F_4$ ;  $F_4 = 90$  corresponds to  $B = 810 \text{ cm}^{-1}$ ).  $h = 1.5$  gives the ligand the same position in the nephelauxetic series as neldamine, which is not unreasonable. The  $f$  of 1.35 places the anion at about the same position in the spectrochemical series as *o*-phenanthroline. It should be noted that the ferrous complex of *o*-phenanthroline is low spin, as are some of the poly(1-pyrazolyl)borates.

The  $\Delta$  value for the octahedral Co(II) complexes has been taken from a previous publication<sup>3</sup> and was obtained as a best fit to the spectrum using matrices for the trigonal potential. The  $\Delta$  value obtained is quite different from the  ${}^4T_1$ - ${}^4A_2$  separation, and, as pointed out above, this difference is probably due to the  ${}^4A_2$ - ${}^4T_1$  interaction under the low symmetry component of the field.  $B$  has been calculated from the estimated separation in the complex<sup>3</sup> ( $= 15B$ ).

The  $\Delta$  value for  $\text{Cu}^{2+}$  is, of course, uncorrected for the Jahn-Teller effect, and the "true"  $\Delta$  is probably somewhat lower. The effects of the trigonal component of the field are probably comparable to any Jahn-Teller effect and have also been neglected. There is considerable uncertainty in the value of  $\Delta$  given for Co(II) in tetrahedral coordination. The  $\Delta$  values for the tetra-

hedral complexes are quite close to  $4/9$  times the  $\Delta$  for the octahedral cases.

The nuclear resonance shifts in the paramagnetic systems relative to the corresponding diamagnetic species must be ascribed to either dipolar or scalar coupling between the electron and nuclear spins. A scalar contribution to the shift requires unpaired spin density in a  $\sigma$  orbital on the proton in question. Four separate mechanisms giving rise to resonance shifts may be identified: (1) delocalization in the  $\pi$  system through  $d\pi$ - $p\pi$  bonding with polarization of the spin in the  $\sigma$  orbital on the proton by unpaired  $p\pi$  spin density, (2) delocalization in the  $\sigma$  system, (3) polarization of metal-ligand bonding orbitals by unpaired spin in metal orbitals of a different symmetry, and (4) the pseudo-contact or dipolar interaction.

It is apparent that the interpretation of these shifts can be a matter of some complexity, and a complete analysis is not possible with the present state of the art. Usually firm conclusions can only be obtained when one of the mechanisms predominates. With the exception of the shifts in the octahedral Co(II) complexes, which are determined largely by the pseudo-contact effect, this is apparently not the case for the present series of compounds. However, the following observations can be made for the data in this paper.

In the complex  $\text{Ni}[\text{B}(\text{pz})_3]_2$ , the proton resonances in the pyrazolyl residue not bonded to the metal are close to those for the diamagnetic zinc complex. The ground state for this complex is  ${}^3A_2$ , and even quite large trigonal distortions in the crystal field would not be expected to give rise to large  $g$ -tensor anisotropies. Dipolar contributions to the shifts are therefore expected to be negligible. The scalar contribution to the shifts on the fourth pyrazolyl residue must also be negligible, indicating that the saturated boron atom is effective in insulating the terminal substituent from the unpaired spin on the metal. The fourth pyrazolyl residue in the corresponding  $\text{Co}^{2+}$  complex shows large downfield shifts. The ground state here is  ${}^4T_1$ , and large anisotropies in the electron moment have been shown to arise from the trigonal component in the field. The shifts in the fourth pyrazolyl residue are therefore due to the dipolar coupling between the proton and electron moments.

An appreciable dipolar contribution for the octahedral ferrous system is also anticipated. This expectation receives some support from the shift to high field of the H on boron in the hydrotris(3,4,5-trimethyl-1-pyrazolyl)borates and hydrotris(3,5-dimethyl-1-pyrazolyl)borates.<sup>2</sup> It is, however, still possible that the shift could arise from spin polarization through the boron. Unfortunately, the  $\text{Fe}[\text{B}(\text{pz})_3]_2$  compound, which would give the best test of this point, is diamagnetic. If the high-field shift of the terminal proton is due to the dipolar interaction, the over-all anisotropy for the  $\text{Fe}^{2+}$  system is indicated to be of the opposite sign to that for  $\text{Co}^{2+}$  where the proton on boron shifts to low field. Interpretations involving the protons attached directly to boron should be viewed with caution since large shifts are found for these protons in the tetrahedral cobaltous complexes where little  $g$  anisotropy is expected.

In conclusion, it may be stated that the optical and magnetic properties of this series of compounds fall

into a consistent pattern. The nmr shifts of the paramagnetic compounds on the other hand do not show pronounced regularities even in such a series of closely related compounds, and it is apparent that several of the possible mechanisms for producing these shifts are combining to give a complex pattern.

## Experimental Section

**A. Susceptibility Measurements.** Susceptibility measurements have been made in solution using an nmr method.<sup>22</sup> Measurements were made in  $\text{CHCl}_3$  or  $\text{CH}_2\text{Cl}_2$ , depending on the solubility. The effective moments have been calculated using room-temperature data and assuming the Curie law is obeyed. The assumption is reasonable for all cases except the octahedrally coordinated Co complexes where a pronounced temperature dependence of effective moment is anticipated. The accuracy of the measurements varies because of the differing solubilities and susceptibilities involved. The variation of susceptibility with temperature could not be measured with sufficient accuracy to permit a meaningful verification of the Curie law behavior because of the limited temperature range which could be investigated.

**B. Optical Measurements.** Optical absorption studies were made in the region 17,000 to 2000 Å using a Cary 14 recording spectrophotometer. Measurements at short wavelengths were made in hexane solution, and the remaining measurements were made in chloroform or dichloromethane. Infrared spectra were obtained using a Perkin-Elmer Model 21 spectrophotometer.

**C. Nmr Spectra.** The nmr spectra were recorded using a Varian HR-60 spectrometer for proton resonance studies of the paramagnetic species and an A-60 for the diamagnetic species. A 14.2-Mcps radiofrequency unit and probe were used for the boron studies. Measurements were made in deuteriochloroform except as noted. The proton shifts are measured  $\alpha$ s. tetramethylsilane as an internal standard. The boron shifts are measured  $\alpha$ s. trimethyl borate as an external standard.

**D. Synthesis of Compounds.** The synthesis of transition metal complexes with unsubstituted poly(1-pyrazolyl)borates<sup>23</sup> and poly(1-pyrazolyl)borates containing substituents on carbon or boron<sup>24</sup> will be published elsewhere.

## Spin Equilibria in Octahedral Iron(II) Poly(1-pyrazolyl)borates

J. P. Jesson, S. Trofimenko, and D. R. Eaton

Contribution No. 1266 from the Central Research Department, Experimental Station E. I. du Pont de Nemours and Company, Wilmington Delaware 19898.  
Received December 7, 1966

**Abstract:** The  $\text{Fe}^{2+}$  complexes based on the hydrotris(1-pyrazolyl)borate ligand provide an example of a "spin equilibrium" between high- and low-spin forms. Fully high-spin, fully low-spin, and complexes of intermediate spin can be produced by appropriate substitution. Optical spectra, susceptibility data, and magnetic resonance experiments leading to the characterization of these equilibria are presented.

The possibility of the occurrence of a thermally accessible electronic state of different multiplicity from the ground state has long been recognized for  $d^4$ ,  $d^5$ ,  $d^6$ , and  $d^7$  ions in octahedral environments.<sup>1</sup> The experimental realization of an equilibrium of this type is determined by the availability of a complex for which the low-spin and high-spin ground states are separated by only a few hundred reciprocal centimeters. Since the energies involved in changes in chemical binding are in general much larger than this, the requirement is very restrictive and accounts for the fact that there are few, if any, well-documented cases of equilibria of this type.

For the  $d^5$  and  $d^6$  configurations, the susceptibility may be taken as the population weighted-average of the susceptibilities of the two terms of different multiplicity. For  $d^4$  and  $d^7$  the situation is more complicated as the spin-orbit coupling connects the two states involved. The presence of low-symmetry components in the crystal field is another factor which must also be considered.

The most favorable case for an unambiguous experimental observation of this type of equilibrium is the

$d^6$  configuration where the low-spin system is diamagnetic and the change in the number of unpaired electrons is four.

The ferrous compounds of structures I–V present such an unambiguous example of a system in which both high- and low-spin ground states are thermally accessible.

sible, without change of molecular geometry. (A possible difference could arise due to a Jahn-Teller distortion in the high-spin state. As indicated in the discussion the large trigonal component in the crystal field leaves an orbital singlet lowest in the high-spin state, and Jahn-Teller effects will probably be small. There will, of course, be a difference in Fe-N bond lengths in the two states.)

Minor changes in molecular structure give rise to very different magnetic properties: fully paramagnetic high-spin compounds ( $\mu_{\text{eff}}$  at room temperature  $\sim 5.2$  BM), and compounds for which the moment is intermediate and strongly temperature dependent. Some are diamagnetic or partially diamagnetic complexes of deeply colored magenta compounds, while the fully paramagnetic compounds are pale green, almost colorless.

Other possible examples of anomalous magnetic behavior close to the crossover point have been reported by Stouffer, *et al.*, for  $\text{Co}^{2+}(\text{d}^7)$ ,<sup>2</sup> Ewald, *et al.*, for  $\text{Cr}^{3+}(\text{d}^3)$ ,<sup>3</sup> and Melson, and Busch<sup>4</sup> for  $\text{Ni}^{2+}(\text{d}^8)$ . More recently a convincing example for  $\text{Fe}^{2+}(\text{d}^6)$  has been reported by König and Madya.<sup>5</sup>

### Magnetic Susceptibilities

The room-temperature moments for some of these complexes measured in solution by an NMR method, together with their molecular weights, are listed in Table I. (The molecular weights were measured in chloroform using the vapor-pressure osmometer technique.) It is clear from these molecular weights that we are dealing with monomeric species. The rigid tridentate character of the ligand eliminates the possibility of a

<sup>a</sup> Measured in  $\text{CH}_2\text{Cl}_2$  because of solubility. All others measured in  $\text{CHCl}_3$ .

The data of Table I show that the first two and last two complexes have moments corresponding essentially to fully low-spin and fully high-spin systems, respectively, and that the remaining complex bis[hydrotris(1-pyrazolyl)borate]iron(II) has an intermediate moment. If this arises from a spin equilibrium it should be strongly temperature dependent. This latter prediction is substantiated by the data shown in Figures 1 and 2. Figure 1 shows plots of the reciprocal molar susceptibility against temperature for the complexes III and V. The diamagnetic compounds cannot, of course, be included in this plot. Compound IV shows essentially the same behavior as V. Figure 2 shows a plot of the effective moments against temperature for complexes I, III, and V, complex I being diamagnetic at all temperatures studied. It appears there is some reduction in the effective moment of complex V with decreasing temperature, possibly indicating some favoring of the diamagnetic form. The moment is close to 5.2 BM at room temperature and about 5.0 BM at the lower temperatures. However, an alternative explanation could be that the  ${}^6\text{E}_g$  component of the split  ${}^6\text{T}_{2g}$

ground state lies lowest and that the temperature dependence of the effective moment is due to varying populations of the sublevels in the E state. The behavior of complex III, though, is only interpretable in terms of a spin equilibrium. The variation of the effective moment with temperature is as nearly intermediate between the high-spin and low-spin cases as one could expect to realize. Several other complexes have also been studied. The compound with  $R = X = H$ ,  $Y = i\text{-Pr}$  showed intermediate behavior analogous to complex III, and the compound with  $R = n\text{-Bu}$ ,  $X = Y = H$  proved to be diamagnetic.

### Optical Spectra

The positions of absorption maxima and the extinction coefficients for these Fe(II) complexes are given in Table II. Results for compound II have been

<sup>a</sup> Measured in cyclohexane.

omitted as the spectrum is closely similar to those of complexes I and III. The relatively small extinction coefficient of the absorption at  $\sim 19,000\text{ cm}^{-1}$  in complex III indicates that it is probably a d-d transition, and since this band is also found in the fully diamagnetic molecule I it must be a singlet-singlet transition. We assign the absorption to the expected  ${}^1T_{1g}({}^1I) \leftarrow {}^1A_{1g}$  transition. It might be noted that complex III is almost completely diamagnetic at room temperature in the solid state. Mössbauer and magnetic susceptibility studies have shown that the same general type of behavior with temperature is observed in the solid as is found in solution. However, the equilibrium has shifted in favor of the diamagnetic form.<sup>7</sup>

The absorption spectra and appearance of complexes IV and V are similar to those of hydrated ferrous salts. Only one d-d transition of any intensity is observed, and as indicated in Table II this is assigned to the  ${}^6E_g \leftarrow {}^6T_{2g}$  transition. In the hydrated ferrous salts this transition usually shows a pronounced doubling which has been ascribed to either Jahn-Teller distortions or to low-symmetry components in the crystal field.<sup>8</sup> In the

present case the band is quite symmetrical and shows no evidence of splitting. The transition should occur at a frequency  $\Delta$ , showing that  $\Delta \approx 12,500\text{ cm}^{-1}$  for the high-spin systems.  $\Delta$  is the octahedral splitting parameter.

The reason for the dramatic color change from pale green to deep magenta on going from fully high-spin to fully low-spin compounds is now clear. The first d-d transition occurs at a much shorter wavelength for the spin-paired compound. This is to be anticipated on the basis of a simple crystal-field calculation, as is shown in the Discussion. The singlet-singlet transition is 20-30 times more intense than the quintet-quintet. This is probably due to intensity borrowing from nearby charge-transfer absorption in the former case. For the high-spin systems, the d-d transition is well separated from the charge-transfer absorption. The charge-transfer absorption is at considerably shorter wavelengths in the high-spin systems. These high-spin chelates all have methyl substituents, and the shift may be ascribed to the hyperconjugative effect of these groups. Hyperconjugation raises the energy of the highest filled ligand  $\pi$  orbital. Thus the ionization potentials of alkyl-substituted ethylenes are lower than that of ethylene. Calculations indicate that the lowest antibonding  $\pi$  orbital is also raised in energy by alkyl substitution, but by a smaller amount so that the energy gap is decreased. This is supported by the red shift in the long wave absorption in ethylene on alkyl substitution. Thus the lowest unfilled ligand orbital is expected to occur at higher energies in the high-spin complexes than in the low-spin complexes. The energies of the d orbitals are unlikely to be grossly different in the high-spin and low-spin complexes. The large blue shift observed on passing from low spin to high spin is therefore consistent with the assignment of these bands to metal-to-ligand charge-transfer transitions.

### Nuclear Magnetic Resonance Spectra

Nmr assignments for the octahedral ferrous complexes are complicated by the high-spin-low-spin equilibrium. The resonances for the 4-H proton in the parent complex and the 3,5-dimethyl complex, which are in essentially the same positions for the Co<sup>2+</sup> derivatives,<sup>9</sup> are very different for the Fe<sup>2+</sup> case since a large proportion of the parent complex is in the diamagnetic state. Assignments have been made mainly on the basis of line intensities and widths, although the effect of substitution can be utilized by comparing complexes IV and V. Chemical shifts at 30° and assignments for the octahedral Fe(II) complexes are given in Table III.

It is clear that the nmr data are in qualitative agreement with the conclusions from the susceptibility data. Thus the resonances in compounds I and II are in the positions anticipated for diamagnetic complexes, the positions of the resonances for the 3-, 4-, and 5-H on the pyrazolyl groups being close to those for the corresponding zinc complexes.<sup>9</sup> Complex III shows intermediate shifts which are compatible with the assumed spin equilibrium, and much larger shifts are observed for the fully paramagnetic complexes IV and V. More direct evidence for the spin equilibrium in complex

Shifts measured from TMS as internal standard.

is provided by the temperature dependence of the shifts. The temperature dependence of the shifts of complexes IV and V (see Figure 3b and c) show the normal Curie-type behavior expected in paramagnetic systems. Complex III, however (Figure 3a), shows the opposite type of behavior, the shifts converging toward diamagnetic positions as the temperature is lowered.

## Discussion

An approximate estimate of the magnitude of the octahedral splitting parameter  $\Delta$  required to induce spin pairing may be obtained by equating the first-order expressions for the energies of the electronic states involved, using the strong-field scheme. The  $\Delta$  found in this way is equal to the mean-pairing energy  $\pi$ . Griffiths<sup>10</sup> has found expressions for the mean pairing energies in these configurations and obtained the following approximate conditions for the occurrence of the low-spin form (in  $\text{cm}^{-1}$ ).

$$\begin{aligned} d^5 \Delta &> 7.5B + 5C \approx 24,000 \\ d^6 \Delta &> 2.5B + 4C \approx 16,400 \text{ (12,500)} \\ d^7 \Delta &> 7B + 4C \approx 20,000 \text{ (10,000)} \end{aligned} \quad (1)$$

The values after the expressions have been calculated using  $B = 800$  and  $C = 4.5B = 3600 \text{ cm}^{-1}$ . The numbers in parentheses are the  $\Delta$  values estimated from the spectra of the octahedral high-spin iron(II) and cobalt(II) poly(1-pyrazolyl)borates.<sup>9</sup> It can be seen that spin pairing is more easily achieved for the  $d^6$  than the  $d^5$  or  $d^7$  configurations.

The absorption at  $12,500 \text{ cm}^{-1}$  in complexes IV and V has been assigned to the transition  ${}^5E_g \rightarrow {}^5T_{2g}$  which simple crystal-field theory has an energy  $\Delta(\text{hs}) = 500 \text{ cm}^{-1}$  (hs = high spin). However, as Ewald, et al.,<sup>3</sup> have pointed out, because of the expected in-

Figure 3. Proton resonance spectra of octahedral ferrous complexes as a function of temperature measured in  $\text{CDCl}_3$  (shifts from TMS at 60 Mcps): (a) compound III, (b) compound IV, (c) compound V.

Figure 4. Tanabe diagram for  $d^6$  configuration. Only the quintet states and the  ${}^1T_{1g}$  and  ${}^1A_{1g}$  states below 35,000  $\text{cm}^{-1}$  have been included. The positions of the experimentally observed high-spin transition and first low-spin transition are indicated in the figure;  $B = 800$  and  $C = 3600 \text{ cm}^{-1}$ .

crease in bond lengths on transferring an electron from the  $t_{2g}$  orbitals (nonbonding) to the  $e_g$  orbitals (antibonding), the  $\Delta$  values for the high- and low-spin states in their equilibrium geometries will be different, and one has the approximate condition

$$\Delta(\text{hs}) < \pi < \Delta(\text{ls}) \quad (2)$$

the  $\Delta$  values referring to the equilibrium situations ( $\text{ls} = \text{low spin}$ ).

Robinson, *et al.*,<sup>11</sup> have made an estimate of the critical  $\Delta(\text{hs})$  value for crossover to the low-spin form by comparison of a series of iron(II) and the corresponding nickel(II) complexes. They note that the ratio  $\Delta_{\text{Fe}^{2+}}/\Delta_{\text{Ni}^{2+}} = 1.11 \pm 0.07$  for a series of five complexes. The weakest ligand which produced spin pairing in the iron(II) complexes gave an extrapolated  $\Delta(\text{hs}) \approx 13,400 \text{ cm}^{-1}$ . The strongest ligand which did not give spin pairing has  $\Delta(\text{hs}) = 11,600 \text{ cm}^{-1}$ . It was therefore estimated that the critical value of  $\Delta(\text{hs})$  is  $12,500 \pm 800 \text{ cm}^{-1}$ , in remarkably good agreement with the value found from the iron poly(1-pyrazolyl)borates. Some variation in the critical value of  $\Delta(\text{hs})$  is possible since the mean pairing energy  $\pi$  depends on the interelectronic repulsion parameters ( $B$  and  $C$ ) which themselves vary with the degree of covalent bonding in the complexes.

The relevant electronic levels of  $d^6$  as a function of crystal-field strength  $\Delta$ , for octahedral coordination, are shown in Figure 4. The levels were calculated us-

ing the matrices of Tanabe and Sugano<sup>12</sup> with  $B = 800$  and  $C = 3600 \text{ cm}^{-1}$ . The choice of values for  $B$  and  $C$  is based on the following considerations. The free ion value of  $B$  for  $\text{Fe}^{2+}$  ( $\sim 940 \text{ cm}^{-1}$ ) is somewhat lower than the values for  $\text{Co}^{2+}$  ( $\sim 980 \text{ cm}^{-1}$ ) and  $\text{Ni}^{2+}$  ( $\sim 1040 \text{ cm}^{-1}$ ).<sup>13</sup> It seems likely that the value in the complex will also be lower. Values of  $B$  of  $\sim 830$  and  $\sim 850$  were found for the corresponding  $\text{Co(II)}$  and  $\text{Ni(II)}$  complexes. A value of  $B = 800 \text{ cm}^{-1}$  for the  $\text{Fe(II)}$  complexes is therefore reasonable. The assumption  $C = 4.5B = 3600 \text{ cm}^{-1}$  leads to a mean pairing energy of  $\pi \approx 16,400 \text{ cm}^{-1}$  from eq 1. The crossover point " $\pi$ " in the full calculations is seen to be  $\sim 15,000 \text{ cm}^{-1}$  rather than the value of  $16,400 \text{ cm}^{-1}$  given by the approximate formula. The difference is due to the interaction between the four  ${}^1A_1$  states of the configuration, which has been neglected in the simple formulas.

The positions of the first high-spin and first low-spin transitions are marked on Figure 4, occurring at  $\Delta(\text{hs}) = 12,500 \text{ cm}^{-1}$  and  $\Delta(\text{ls}) = 21,000 \text{ cm}^{-1}$ . In view of the neglect of the low-symmetry component of the field, the uncertainty in the values of the interelectronic repulsion integrals, and the fact that they are assumed to have the same value for high- and low-spin compounds, there may be considerable error in the  $\Delta(\text{ls})$  value. In the iron(III) dithiocarbamates, Ewald, *et al.*,<sup>3</sup> found that their electronic spectral data gave a quite low value for  $\Delta(\text{hs}) \approx 12,800 \text{ cm}^{-1}$ . This value is even lower than  $\Delta$  for  $\text{Fe(H}_2\text{O)}_6^{3+}$ . A similar situation was noted in the  $\text{Co(II)}$  complexes of Stouffer, *et al.*<sup>2</sup> The results of Ewald, *et al.*,<sup>3</sup> were rationalized in terms of a very large nephelauxetic effect with  $B(\text{complex})/B(\text{free ion}) = \beta \approx 0.47$ . Values of  $\beta$  and  $\Delta$  could not be obtained directly from electronic spectral data and were estimated by comparison of optical data for other dithiocarbamates with the corresponding hexaquo complexes.

In the present case  $\Delta(\text{hs})$  is already considerably larger than  $\Delta[\text{Fe(H}_2\text{O)}_6^{2+}]$ ,  $\sim 10,400 \text{ cm}^{-1}$ . The  $\beta$  value, on the basis of our assumption that the reduction in  $B$  is similar to that found in the  $\text{Co(II)}$  and  $\text{Ni(II)}$  cases,<sup>9</sup> is  $\sim 0.85$ .

It is anticipated that in the complex  $\text{Fe[HB(pz)}_3\text{)]}_2$  which has  $D_{3d}$  symmetry, there will be a large trigonal component in the crystal field. Such a trigonal component has been established for  $\text{Co[HB(pz)}_3\text{)]}_2$ , and it has been shown that the splitting of the  ${}^4T_{1g}$  ground state is approximately  $2000 \text{ cm}^{-1}$  with the orbital doublet lying lowest.<sup>14</sup> It is also anticipated that the orbital splitting of the  ${}^5T_{2g}$  state in  $\text{Fe[HB(pz)}_3\text{)]}_2$  due to this trigonal component will have the opposite sign to that of the  $\text{Co(II)}$  complex, giving an orbital singlet as the lowest component.<sup>15</sup> This follows from simple one-electron theory since the high-spin  $d^7$  system has a single hole in the  $t_{2g}$  shell, and the high-spin  $d^6$  ground state is degenerate owing to a single electron in the  $t_{2g}$  shell. However, it has been suggested that the inclusion of Coulomb and exchange interactions can reverse the sign of the ground-state splitting for  $\text{Co}^{2+}$ .<sup>16</sup> In addition the assumption that the low-symmetry

Level scheme for ground-state manifold of  $\text{Fe}[\text{HB}(\text{pz})_3]_2$ .

ent of the crystal field is of the same form for and  $\text{Fe}^{2+}$  cases may not be completely justice the orbital degeneracy of the ground state the interpretation of the susceptibility data, the ntal evidence bearing on this point will be l.

agnetic resonance experiments for  $\text{Fe}^{2+}$  and the cadmium chloride lattice give the following

$$\begin{array}{lll} \text{Fe}^{2+} & g_{\parallel} = 7.4 & g_{\perp} = 0? \\ \text{Co}^{2+} & g_{\parallel} = 3.06 & g_{\perp} = 4.98 \end{array}$$

results have been obtained in this laboratory me ions in  $\text{MgTiO}_3$ .

$$\begin{array}{lll} \text{Fe}^{2+} & g_{\parallel} \approx 12 & g_{\perp} = 0? \\ \text{Co}^{2+} & g_{\parallel} = 2.78 & g_{\perp} = 5.02 \end{array}$$

surements were made on powders at 4.2°K, e is considerable uncertainty in the  $g_{\parallel}$  value due to the breadth of the absorption. In s the  $\text{Co}^{2+}$  results show unambiguously that al singlet lies lowest in the split ground state.<sup>18</sup> esponding treatment for the  ${}^5\text{T}_{2g}$  state of  $\text{Fe}^{2+}$  given by Griffiths.<sup>13</sup>  $g_{\parallel}$  varies from about 4 depending on the magnitude and sign of the pponent in the crystal field.  $g_{\perp} = 0$ . Values ween 7 and 10 correspond to the orbital doublet rest, suggesting that this is the case for the d  $\text{MgTiO}_3$  systems. This interpretation could lated in the even-electron  $\text{Fe}^{2+}$  system by the of rhombic components in the crystal fields. tal structures for the two cases demand ac-rigonal symmetry about the metal in the host

The substitution of the  $\text{Fe}^{2+}$  impurity could : slight rhombic components into the fields. cult to say whether the distortions would be y large to reverse the assignment. Thus the etic resonance data do seem to indicate that nd-state splittings for  $\text{Fe}^{2+}$  and  $\text{Co}^{2+}$  in the onal field are of the opposite sign, and for the liscussion we shall therefore assume that the of the orbital triplet in the ferrous poly(1-)borates is large and leaves an orbital singlet

Figure 6. Plot of free energy against temperature for spin equilibrium in  $\text{Fe}[\text{HB}(\text{pz})_3]_2$ .

A schematic energy level diagram based on this assumption is shown in Figure 5. The spin equilibrium involves the  ${}^5\text{A}_{1g}$  and  ${}^1\text{A}_{1g}$  states. Diagrams such as Figure 5 must be viewed with caution when temperature studies are involved since the level scheme may be a fairly sensitive function of temperature. If  ${}^5\text{A}_{1g} \leftrightarrow {}^1\text{A}_{1g}$  separation varies approximately linearly with temperature, the effect will appear as an entropy term when the free energy of the equilibrium is considered. Such an effect can also be produced by differences in the vibrational partition functions for the high-spin and low-spin states.<sup>3</sup> In a previous paper it was suggested<sup>6</sup> that an appreciable entropy term in the apparent free energy for an equilibrium of this type would argue for a geometrical difference between the species involved. The arguments given above, however, suggest that this is not the only possible origin of the term.

Splitting of the  ${}^5\text{A}_{1g}$  state due to spin-orbit effects and the low-symmetry component of the field will be of the order of tens of wavenumbers, and for our purposes the state will behave as a simple spin quintet with  $g \sim 2$ .  $g$  will be slightly larger than 2 owing to spin-orbit mixing from excited states, and a value of 2.13 is obtained from the moment of the fully paramagnetic complex.

The susceptibility of the system as a function of temperature is then given by

$$\chi_M = \frac{Ng^2\beta^2S(S+1)}{3kT} [e^{\Delta G/RT} + 1]^{-1} \quad (3)$$

$\Delta G$  being the molar free-energy change in the process. The expression may be written in terms of the effective moments as

$$\Delta G = RT \ln \left[ \frac{\mu_{\infty}^2}{\mu^2} - 1 \right] \quad (4)$$

where  $\mu_{\infty}$  is the moment for the fully paramagnetic form, and this is taken as 5.22 BM from the moment of V.

. Orton, *Rept. Progr. Phys.*, **22**, 204 (1959).

.bragam and M. H. L. Pryce, *Proc. Roy. Soc. (London)*, **1951**.

In Figure 6 the free-energy change for the spin equilibrium in  $\text{Fe}[\text{HB}(\text{pz})_3]_2$  is plotted against temperature, giving  $\Delta H = 3.85$  kcal/mole and  $\Delta S = 11.4$  eu. If our assumptions about the energy level scheme are correct, the entropy term of 11.4 eu will contain a contribution  $R \ln 5 = 3.2$  eu due to the spin degeneracy of the quintet state but no contribution from orbital degeneracy. The remaining 8.2 eu must be accounted for in terms of a temperature dependence of the effective crystal field, variable solvation effects, and differences in the vibrational partition functions between the two states.

There are two possible mechanisms for the paramagnetic shifts observed in the nuclear resonance spectra. Spin delocalization to the ligand can result in a Fermi contact interaction, the shifts being given by an expression of the form

$$\Delta\nu_i = -a_i \frac{2\pi g\beta\nu S(S+1)}{3kT\gamma} \quad (5)$$

where  $a_i$  is in cycles per second. The expression is based on the assumption of a Curie law magnetic behavior of the ground state, a situation which is seldom if ever realized in paramagnetic compounds showing well-resolved nmr spectra.

The second mechanism involves the dipolar coupling of the electron and nuclear magnetic moments and gives a net shift for the nuclear resonances in solution only if the electron moment is anisotropic. With the limiting assumption of a Curie law situation, an expression of the form

$$\Delta\nu = -\frac{1}{15}\nu \left( \frac{3\cos^2\theta - 1}{r_i} \right) \frac{\beta^2 S(S+1)}{3kT} [g_{\parallel} - g_{\perp}] [3g_{\parallel} + 4g_{\perp}] \quad (6)$$

is derived. The additional assumption has been made, in averaging over the tumbling motion, that the spin-

lattice relaxation time is short relative to the correlation time for tumbling. This situation is likely to apply to cases where well-resolved nmr spectra are observed since we have the criterion  $T_1^{-1} \gg a_i$ , required for sharp spectra,  $T_1$  being the electron spin-lattice relaxation time and  $a_i$  the electron-nuclear hyperfine coupling constant.

If either or both types of interaction are present, the shifts are inversely proportional to temperature for the paramagnetic species. The diamagnetic-paramagnetic equilibrium can be allowed for by the factor  $[e^{\Delta G/RT} + 1]^{-1}$  as in the susceptibility equations. Quite large anisotropies can be induced in the  ${}^5\text{T}_2$  ground state by low-symmetry components in the field,<sup>13</sup> and it would be unwarranted to assume that the observed shifts are due only to the scalar interaction. In addition to the departures from the simple  $1/T$  behavior due to the spin equilibrium, departures can also be produced by non-Curie law behavior. Differences in  $g$ -tensor components and hyperfine coupling constants for the split levels of the ground state would require a more complicated Boltzmann averaging, giving a relatively complex temperature dependence.

In view of the limitations imposed on the formulas and the difficulty in establishing the proton shifts for the fully paramagnetic system, the data do not seem to merit analysis in terms of an enthalpy and entropy change for the equilibrium.

## Experimental Section

The epr measurements were made using a Varian 100-kcps X-band spectrometer equipped with a 12-in. magnet having a fixed 1.75-in. gap. Field measurements were made using a Harvey Wells FC-502 gaussmeter and CMC 709C frequency counter. Frequency measurements were made with a Hewlett-Packard X5332A frequency meter. A quartz helium finger was used to maintain the samples at 4.2°K.

Other experimental techniques used have been described in a previous paper.<sup>9</sup>

## Boron-Pyrazole Chemistry. I. Pyrazaboles

S. Trofimenko

Contribution No. 1238 from the Central Research Department, Experimental Station, E. I. du Pont de Nemours and Company, Wilmington, Delaware 19898.

Received January 5, 1967

**Abstract:** Boranes and borane complexes react cleanly with pyrazoles giving rise to nondissociable dimers of 1-borylpyrazoles. These compounds represent a new, remarkably stable class of boron heterocycles and have been named pyrazaboles. One-step syntheses of representative pyrazaboles are described and their properties are discussed.

In 1924 Morgan and Tunstall<sup>1</sup> found that a  $\text{BF}_2$  group can replace the hydrogen bridge in acetylacetone, benzoylacetone, and dibenzoylmethane. The stability of the products has been attributed to coordination of the  $\text{BF}_2$  group with the second heteroatom. At that time other examples of a  $\text{BR}_2$  group ( $\text{R} = \text{Cl}$ , alkoxy, alkyl, aryl;  $\text{R}_2 = o$ -phenylenedioxy) replacing the chelated proton in enolizable  $\beta$ -diketones,<sup>2-12</sup>  $\beta$ -keto esters,<sup>9b,10,12</sup>  $\beta$ -ketocarboxamides,<sup>14</sup> etoimines,<sup>9b,10,15</sup> 8-hydroxyquinoline,<sup>10,12,16-19</sup> binide,<sup>20</sup> 1-amino-7-imino-1,3,5-cycloheptatrienes,<sup>21</sup> (dimethylglyoxime)nickel<sup>22</sup> and -cobalt,<sup>23</sup> as well as cellaneous chelating agents with N and O terminals<sup>24,25</sup> have appeared. The notion that a  $\text{BR}_2$  group, when bonded to one heteroatom of a chelating agent and coordinated to the other, resembles in some ways a metal ion is implicit in the above results and has been mentioned by several of the authors. It is further supported by the finding that  $\text{BF}_2$ -bridged acetylacetone

undergoes electrophilic substitution reactions<sup>26</sup> akin to those of transition metal acetylacetonates for which quasi-aromaticity has been invoked.<sup>27</sup>

In all these compounds the  $\text{BR}_2$  group forms an intramolecular bridge. We were interested in constructing resonance-stabilized cyclic structures of high symmetry based on *intermolecular*  $\text{BR}_2$  bridges. Pyrazole was selected for this purpose since its geometry was known to favor formation of hydrogen-bonded dimers<sup>28</sup> and since both its cationic and anionic forms possess  $\text{C}_{2v}$  symmetry.<sup>29</sup> In addition this heterocyclic nucleus has great hydrolytic and oxidative stability. With pyrazole dimer as the starting point, it was assumed that this entity could be bridged by any binary combination chosen from (a) hydrogen, (b) transition metal ion, and (c)  $\text{BR}_2$  group, the interchangeability of these in chelating systems having been amply demonstrated. Structures I-VI were arrived at in this fashion. Of these, the first two are known examples of pyrazole dimer and

transition metal compounds with pyrazole,<sup>30</sup> respectively. Compounds IV and V are hydrogen and metal poly(1-pyrazolyl)borates<sup>31</sup> and are dealt with elsewhere.<sup>32</sup>

This paper is concerned with compounds of type III which, because of their unusual features, stability, and wealth of derivatives, were given the trivial name "pyrazabole" with numbering as shown in structure X.

## Results and Discussion

Refluxing equimolar amounts of pyrazole and trimethylamine borane in toluene resulted in rapid evolution of hydrogen and trimethylamine (eq 1, X = Y = H). A crystalline, sublimable solid of camphoraceous odor, mp 80–81°, was isolated in good yield. It was a dimer of 1-dihydroborylpyrazole as established by elemental analysis, molecular weight determination, the presence of a strong BH<sub>2</sub> multiplet around 2400–2500 cm<sup>-1</sup> in the infrared, and the degradation of this compound by boiling hydrochloric acid to pyrazole and boric acid.

Of the three *a priori* possible structures, VII (X = Y = H), VIII, and IX, one would immediately tend to select VII for electronic and steric reasons.<sup>33</sup> Support for this structure was obtained from H<sup>1</sup> nmr which had

only two C–H peaks: a doublet at  $\tau$  2.49 and a triplet at  $\tau$  3.83 ( $J = 2.0$  cps) in a 2:1 ratio. This is obviously incompatible with structures VIII and IX, both of which should display spectra characteristic of asymmetrically substituted pyrazole.<sup>34</sup> The nmr spectrum of pyraza-

(33) As far as VIII is concerned, no precedent is known for electron donation by the substituted nitrogen in 1-alkylpyrazoles. Reactions such as quaternization invariably take place at the 2 position, thus maintaining resonance in the pyrazole ring which would otherwise be lost. Values for the resonance energy of pyrazole range, depending on the method used, were from 27 to 41 kcal/mole: H. Zimmerman and H. Geisenfelder, *Z. Elektrochem.*, **65**, 368 (1961); A. F. Bedford, P. B. Edmondson, and C. T. Mortimer, *J. Chem. Soc.*, 2927 (1962). Moreover, VII should be favored over VIII by some additional 26 kcal/mole from strain considerations, using the thermochemical strain energy for cyclobutane of 26.2 kcal/mole: S. Kaarsemaker and J. Coops, *Rec. Trav. Chim.*, **71**, 261 (1952). With regard to IX, no precedent is known for a simple aminoborane containing hydrogen bridges; such bridges are always broken in the presence of donor atoms.

(34) Proton nmr was shown to be a reliable and discriminating tool for establishing the type of substitution in pyrazole. See, for instance, L. G. Tensmeyer and C. Ainsworth, *J. Org. Chem.*, **31**, 1878 (1966), and

bole indicates equivalence of positions 1, 3, 5, 7. This spectroscopic equivalence persists in all pyrazabole derivatives and is indicative of a structure such as X containing tetrahedral boron in a symmetrical environment. This structure would contain positive charges delocalized in the ligand and negative charges on boron much like the analogous  $\beta$ -diketonates, which is consistent with the inertness of pyrazabole to sodium hydroxide and other nucleophiles.<sup>35</sup>

When substituted pyrazoles were used instead of pyrazole, the reaction proceeded analogously and C-substituted pyrazaboles were obtained (Table I). Pyrazoles with strong electron-withdrawing substituents reacted at a slower rate, commensurate with the reduced nucleophilicity of the 2-nitrogen. In the case of 3,5-bis(trifluoromethyl)pyrazole the product was trimethylamine 3,5-bis(trifluoromethyl)pyrazol-1-ylborane (XI), which could be distilled without decomposition. 1,3,5,7-Tetrakis(trifluoromethyl)pyrazabole (as well as 1,2,3,5,6,7-hexabromopyrazabole) was prepared by using tetrahydrofuran–borane complex instead of trimethylamine borane.

Trialkylboranes react with pyrazoles on heating to 120–150° with evolution of the appropriate hydrocarbon and formation of 4,4,8,8-tetraalkylpyrazaboles (Table

II), while triphenylborane yields 4,4,8,8-tetraphenylpyrazabole.

All pyrazaboles thus prepared are colorless, sublimable solids except for 4,4,8,8-tetrabutylpyrazabole which is a liquid. They are unaffected by air and water and have been stored for over 3 years without any apparent deterioration, although 2,6-dinitropyrazabole is photosensitive.

Such extraordinary stability is even more noteworthy if one considers that none of the other chelating systems has yielded isolable BH<sub>2</sub>-bridged species despite several attempts at their preparation.<sup>13,22</sup> This stability (thermodynamic as well as kinetic) may be rationalized as follows. (A) Molecular models<sup>26</sup> show that the nitrogen and boron atoms (the prospective targets of electrophilic and nucleophilic attack, respectively) in pyrazabole are much better shielded than the BR<sub>2</sub> group and the corresponding heteroatoms in, for instance, analogous acetylacetone derivatives. The im-

portance of steric factors in B–N coordination chemistry is well known.<sup>27</sup> (B) While there are four nonexcited resonance structures based on charge separation in BR<sub>2</sub>-bridged acetylacetone, there are 16 structures such as IIIa in pyrazabole with attendant stabilization of the ground state. (C) The pyrazole nucleus is much more resistant to reduction than an enolizable 1,3-dione system.

A characteristic feature in the infrared spectra of B-unsubstituted pyrazaboles is the strong absorption due to BH stretch (Figure 1). It is most complex in pyrazabole itself and consists of peaks at 2470, 2430, 2410, 2370, 2310, 2280, 2250, and 2240 cm<sup>-1</sup>. The strongest peak is at 2470 cm<sup>-1</sup>, and the remaining ones are of gradually decreasing intensity, except for the 2310, 2280 cm<sup>-1</sup> pair where the higher frequency peak is the weaker of the two.<sup>28</sup> Most C-substituted pyrazaboles have a strong sharp doublet in the 2400–

(37) T. D. Coyle and F. G. A. Stone, *Progr. Boron Chem.*, **1**, 132 (1964), and references cited therein.

(36) While Stuart–Breigle models may not give an accurate picture of the molecular structure, they are useful in supplying qualitative data. An unstrained model of pyrazabole is puckered in the boat form, whereas one would expect the molecule to be planar if coplanarity of the B–N bonds and tetrahedral angles around boron are preserved. Such a model may be also constructed, but it entails considerable strain.

(38) This spectrum was measured in Nujol mull. The BH<sub>2</sub> band remained complex even in CCl<sub>4</sub> solution: 2440 (s), 2415 (s), 2345 (m), 2280 (w), 2265 (w), and 2220 (w) cm<sup>-1</sup>. This complexity of the BH stretch is inconsistent with a planar model of essentially D<sub>2h</sub> symmetry and supports a puckered structure as indicated by molecular models.

<sup>a</sup> Recrystallized from ethanol. <sup>b</sup> Recrystallized from xylene. <sup>c</sup> Recrystallized from heptane. <sup>d</sup> Distilled, bp 94-98° (4.5 mm). <sup>e</sup> Molecular weights determined osmotically in chloroform. <sup>f</sup> The H<sup>1</sup> nmr spectra show: multiplicity, chemical shift in  $\tau$ , and relative areas. The B<sup>11</sup> nmr data are given in parts per million and referred to external methyl borate.

2500-cm<sup>-1</sup> range, separated by 10-100 cm<sup>-1</sup>, and additional weaker and less well-defined bands in the 2250-2400-cm<sup>-1</sup> range. Other functional groups attached to carbon in pyrazaboles absorb normally. For instance,

Figure 1. Infrared spectra of pyrazabole and 4,4,8,8-tetraethylpyrazabole.

2,6-pyrazaboledicarbonitrile contains the CN band at 2260 cm<sup>-1</sup>, as does 4-pyrazolecarbonitrile. Many 4,4,8,8-tetraethylpyrazaboles have characteristic strong

absorption in the 840-880-cm<sup>-1</sup> range and a weaker band at about 910 cm<sup>-1</sup>.

The H<sup>1</sup> nmr spectra of pyrazaboles were most useful in structure assignment. They invariably indicated equivalence of the 1,3,5,7 and 2,6 positions, respectively. The chemical shift of the 1,3,5,7-hydrogens in 2,6-disubstituted pyrazaboles ranges from  $\tau$  0.95 (Y = CN) to 2.64 (Y = CH<sub>3</sub>) and seems to parallel the inductive effect of the substituents. The same trend is noted, but to a lesser extent, in 2,6-disubstituted 4,4,8,8-tetraethylpyrazaboles. Ethyl groups in the latter compounds appear as a relatively narrow triplet (half-height width 10-12 cps) around  $\tau$  9.30-9.40, the methylene hydrogens coinciding with the methyl group (Figure 2). In 1,3,5,7-tetramethyl-4,4,8,8-tetraethylpyrazabole and 1,2,3,5,6,7-hexamethyl-4,4,8,8-tetraethylpyrazabole, the methylene and methyl peaks appear as an ill-defined multiplet in the  $\tau$  9.0-9.8 range. 1,2,3,5,6,7-Hexabromo-4,4,8,8-tetraethylpyrazabole is the only compound having the normal quadruplet-triplet pattern for its ethyl groups. The hydrogens of the BH<sub>2</sub> group in pyrazaboles appear as an exceedingly broad (300 cps) band, but their presence and ratio to other hydrogens is easily established by integration.

The B<sup>11</sup> nmr spectra of pyrazaboles show the expected 1:2:1 triplet in the 27-31-ppm range.<sup>39</sup> In some cases

(39) This is close to the range reported for trimethylamine borane: D. F. Gaines and R. Schaefer, *J. Am. Chem. Soc.*, **86**, 1505 (1964).

are well resolved with coupling constants around cps; in others the triplets are ill defined. In 8-tetraethylpyrazaboles the boron resonance appears as a singlet in the 15–17-ppm range, which is 13 ppm higher than for the  $\text{BEt}_2$ -bridged acetylates,<sup>6</sup> but about 18 ppm lower than in tetraethyl-ion.<sup>40</sup>

With regard to the mechanism of pyrazabole formation two situations may be distinguished. Before considering these, one should note that the geometry of the molecule is favorable to a cyclic five-center transition

If one assumes coordination at the 2 position to precede any bond breaking, the 1-hydrogen should be sufficiently close to an R group to permit intramolecular departure of  $\text{RH}$ . Such proximity may be indicated<sup>41</sup> from the facile formation of a pyrazole formaldehyde adduct<sup>42</sup> possessing an intramolecular hydrogen

and the ease of intramolecular quaternization of 1-(2,3-dibromopropyl)pyrazole.<sup>43</sup> The reaction scheme as shown above is the most plausible path for trialkylboranes, triarylboranes, and tetrahydrofuran where uncontested B–N coordination takes place, as manifested by heat evolution and dissolving pyrazoles suspended in xylene upon addition of trialkylborane. The 1-dialkylborylpyrazole fragment separates apart from dimerizing, react with pyrazole to form a pyrazabole. It has been shown,<sup>35</sup> however, that hydrogen poly(pyrazolyl)borates disproportionate irreversibly at elevated temperatures to pyrazaboles and pyrazole. Moreover, the electrophilicity of a  $\text{BR}_2$  group is not as great as that of pyrazole hydrogen, and hence the probable formation of IV is of minor significance. The molecular activation by coordination suggested here has its analogy in the reaction of boranes with carboxylic acids, the mechanism of which has been proposed by Brown<sup>44</sup> and confirmed by Toporcer, Y, and Green.<sup>45</sup> While the transition state in the pyrazole reaction involves a five-membered ring, the electrons are relayed along pyrazole's  $\pi$  system in that sense an eight-membered ring is involved in the transition state.

A different situation obviously exists when pyrazoles react with trimethylamine borane where a strong donor molecule is involved. Probably an equilibrium involving trimethylamine 1-pyrazolylborane is established, the reaction being driven to completion by removal of trimethylamine from the system and irreversible formation of a pyrazabole.

The reaction of 1,2,4-triazole with triethylborane and the analogous 4,4,8,8-tetraethyl-*sym*-triazabole compound was obtained in lower yield than the corresponding pyrazabole, which is not surprising

Figure 2. Nmr spectrum of 4,4,8,8-tetraethylpyrazabole.

in view of the additional nitrogen atom than can interact in the coordinating stage of the reaction.

## Experimental Section

Pyrazole, 3,5-dimethylpyrazole, 1,2,4-triazole, triethylborane, tributylborane, triphenylborane, and trimethylamine borane are commercially available. They were used without further purification. 4-Chloropyrazole,<sup>46</sup> 4-bromopyrazole,<sup>47</sup> 4-methylpyrazole,<sup>48</sup> 4-pyrazolecarbonitrile,<sup>49</sup> 4-nitropyrazole,<sup>50</sup> 3,4,5-trimethylpyrazole,<sup>51</sup> and 3,4,5-tribromopyrazole<sup>52</sup> were prepared by published methods.

**General Method for Preparing Pyrazaboles.** Equimolar amounts of the appropriate pyrazole and trimethylamine borane were refluxed in toluene (about 1 l./mole). The emanating gases were conducted through a  $-80^\circ$  trap to a wet-test meter or other suitable volumetric device. The progress of the reaction was followed by measuring the amount of hydrogen evolved. In most instances the reaction was complete within a few hours. The solvent was distilled under aspirator vacuum, and the residue was purified by recrystallization and sublimation (see Table I). In the cases of 3,5-bis(trifluoromethyl)pyrazole and 3,4,5-tribromopyrazole, their tetrahydrofuran solutions were added, under nitrogen, to an equivalent amount of borane in tetrahydrofuran. The theoretical amount of hydrogen was evolved rapidly. The solutions were then processed as above.

**General Method for Preparing 4,4,8,8-Tetraethylpyrazaboles.** Equimolar amounts of the appropriate pyrazole and triethylborane were stirred and refluxed in xylene (about 1 l./mole) until the theoretical amount of ethane, as measured by a wet-test meter, was evolved. The solvent was evaporated and the residue purified by recrystallization and sublimation (see Table II).

**4,4,8,8-Tetraethylpyrazabole.** A mixture of 13.6 g of pyrazole and 50 ml of tributylborane (both 0.2 mole) was stirred and refluxed in 250 ml of xylene until about 5 l. of butane was evolved. The solvent was evaporated at reduced pressure, and the residual oil was distilled *in vacuo*. There was obtained 34.2 g (89.0%) of material, bp  $190^\circ$  (4.6 mm),  $n_D^{20}$  1.4948. *Anal.* Calcd for  $\text{C}_{22}\text{H}_{28}\text{B}_2\text{N}_4$ : C, 68.8; H, 10.9. Found: C, 69.0; H, 10.9.

The nmr spectrum consists of a doublet at  $\tau$  2.42 ( $J$  = 2.5 cps), a triplet at 3.62 ( $J$  = 2.5 cps), and a multiplet around 9.2 in 2:1:18 ratio.

**4,4,8,8-Tetraphenylpyrazabole.** A mixture of 22.6 g (0.0935 mole) of triphenylborane and 68 g (1.0 mole) of pyrazole was heated to reflux until benzene ceased to distill. The melt was poured into 800 ml of water and stirred for 2 days. The mixture was filtered, and the solid was air dried and recrystallized from 200 ml of boiling toluene. It was washed with ether and air dried. There was obtained 15.7 g (72.4%) of a material melting at  $273-274^\circ$ . *Anal.* Calcd for  $\text{C}_{30}\text{H}_{18}\text{B}_2\text{N}_4$ : C, 77.6; H, 5.60; N, 12.0. Found: C, 77.9; H, 5.40; N, 11.6.

**3,5-Bis(trifluoromethyl)pyrazole.** A. Adduct of 1,1,1,5,5,5-Hexafluoropentane-2,4-dione with Hydrazine. 1,1,1,5,5,5-Hexafluoropentane-2,4-dione (208 g, 1.00 mole) was added slowly at

5° to a solution of 60 g (1.2 moles) of hydrazine hydrate in 1.5 l. of ethanol. The solution was evaporated at 40° (20 mm), yielding a white solid which was recrystallized from toluene. Two crops, 148 and 15 g, were obtained for a total yield of 72%. The material was purified further by sublimation and melted at 133–135°. *Anal.* Calcd for  $C_5H_6F_4N_2O_3$ : C, 25.0; H, 2.50; F, 47.5. Found: C, 24.9; H, 2.73; F, 47.5.

B. The above product (173 g, 0.72 mole) was melted and heated with stirring as water distilled slowly. After cessation of water evolution, the temperature rose and a material boiling at 147–149° (1 atm) came over and solidified. It melted at 84°, had an unpleasant, pungent odor, and sublimed with great ease. *Anal.* Calcd for  $C_5H_5F_4N_2$ : C, 29.4; H, 0.98; F, 56.0; mol wt, 204. Found: C, 29.5; H, 1.20; F, 56.2; mol wt (cryoscopic in benzene), 208.

Trimethylamine 3,5-Bis(trifluoromethyl)pyrazol-1-ylborane. A mixture of 3,5-bis(trifluoromethyl)pyrazole (20.4 g, 0.100 mole) and trimethylamine borane (7.3 g, 0.10 mole) was refluxed over-

night in 150 ml of toluene. The solvent was distilled at atmospheric pressure leaving an oil. On vacuum distillation there was obtained 21.4 g (78%) of product, bp 88° (1 mm). *Anal.* Calcd for  $C_5H_5F_4N_2$ : C, 34.9; H, 4.37; F, 41.5; N, 15.3. Found: C, 35.2; H, 4.47; F, 42.2; N, 15.2.

The infrared spectrum has a  $BH_3$  multiplet in the 2500- $cm^{-1}$  region. The nmr spectrum shows two singlets at  $\tau$  3.12 and 7.41 with relative intensity of about 1:9.

4,4,8,8-Tetraethyl-sym-triazabole. A mixture of 13.8 g of 1,2,4-triazole and 28 ml of triethylborane (both 0.2 mole) in 250 ml of xylene was stirred and refluxed overnight. The solution was evaporated to dryness, and the residue was sublimed *in vacuo*. The product was obtained, after recrystallization from heptane and resublimation, in 14-g (50%) yield. It melts at 163–164°. *Anal.* Calcd for  $C_{12}H_{14}B_2N_4$ : C, 52.5; H, 8.77; N, 30.7. Found: C, 52.5; H, 8.66; N, 31.2.

The nmr spectrum has a single sharp peak at  $\tau$  1.74 and a multiplet around  $\tau$  9.35 with relative intensities 1:5.

## Boron-Pyrazole Chemistry. II. Poly(1-pyrazolyl)borates

S. Trofimenko

Contribution No. 1268 from the Central Research Department, Experimental Station, E. I. du Pont de Nemours and Company, Wilmington, Delaware 19898.

Received January 5, 1967

**Abstract:** Alkali metal dihydrobis(1-pyrazolyl)borates, hydrotris(1-pyrazolyl)borates, and tetrakis(1-pyrazolyl)borates have been prepared from alkali metal borohydrides and pyrazole. The first two are parent compounds, each representing a new class of chelating agents. Dihydrobis(1-pyrazolyl)borates are uninegative bidentate ligands and react with divalent transition metal ions forming square-planar or tetrahedral chelates, while hydrotris(1-pyrazolyl)borates are uninegative tridentates yielding octahedral coordination compounds. A study of the solvent and cation dependence in the nmr spectra of poly(1-pyrazolyl)borate ions permitted assignment of the 3-H and 5-H doublets. All alkali metal poly(1-pyrazolyl)borates can be converted to isolable free acids of moderate stability. The synthesis and properties of representative compounds are described.

It has been shown recently<sup>1,2</sup> that when a  $BR_2$  group acts as a bridging unit between two pyrazole nuclei, several new classes of boron compounds are obtained, depending on the nature of the second bridging unit.<sup>3</sup> When that unit, Z, is  $BR_2$ , then the resulting structure is a pyrazabole (I). When Z is a metal or onium ion, the compound belongs to the class of poly(1-pyrazolyl)borates (II). Finally, when Z is a hydrogen bridge, we have the corresponding free acid (III).

Pyrazaboles (I) are neutral heterocycles that may be regarded as dimers of an intermediate dihydroboryl-pyrazole (for  $R = H$ ) fragment. On the other hand,

poly(1-pyrazolyl)borates belong to the class of uninegative tetrasubstituted boron compounds which hitherto have been known only as salts. Of these, there are only a few examples of  $[BR_nR'_4-n]^-$  species containing a B–N bond, N being an amino, pyrrolyl, or indolyl group. None of these has displayed any unusual properties.<sup>4–8</sup>

By contrast, poly(1-pyrazolyl)borates not only exhibit remarkable hydrolytic and oxidative stability but are excellent chelating agents for a wide range of transition metals and provide for the first time examples of isolable, albeit hydrated, free acids,  $H[BR_nR'_4-n]$ . This paper is concerned with the synthesis and properties of the two parent ligands, dihydrobis(1-pyrazolyl)borates<sup>9</sup> and hydrotris(1-pyrazolyl)borates,<sup>9</sup> and their free acids and diverse salts and chelates derived therefrom. Although tetrakis(1-pyrazolyl)borates<sup>9</sup> are, in terms of coordinating ability, merely a substituted variant of tris(1-pyrazolyl)borates, they will be covered

(9) For the sake of brevity the dihydrobis(1-pyrazolyl)borate, hydrotris(1-pyrazolyl)borate, and tetrakis(1-pyrazolyl)borate ions will be written as  $H_2B(pz)_2^-$ ,  $HB(pz)_3^-$ , and  $B(pz)_4^-$ , respectively, "pz" denoting the 1-pyrazolyl fragment.

(2) S. Trofimenko, *ibid.*, **89**, 3165 (1967).

(3) One could, of course, view this field from the aspect of a bidentate pyrazolyl group acting as a bridge between two  $BR_2$  groups or between  $BR_2$  and a metal ion. Analogies in the former case are numerous with hydrogen, dialkylamino, alkylmercapto, and other groups acting as bridges. To the latter belong the few examples of hydrogen-bridged metal borohydrides: B. D. James, R. K. Nanda, and M. G. H. Wattbridge, *J. Chem. Soc., Sect. A*, 182 (1966), and references cited therein.

aper since they are preparatively related to the 1 they also fit the  $[H_nB(pz)_4 - n]^-$  formula.

## and Discussion

potassium borohydride is added to an excess n pyrazole, evolution of hydrogen commences. ues smoothly at 90–120° and comes, essentially, when 2 equiv of hydrogen has been evolved. ing the melt into toluene, the salt IV, mp 171–precipitated in 74% yield. This salt may be lized from anisole.

the other hand, the above reaction mixture is urther, a third equivalent of hydrogen is evolved 10°, and the salt V can be isolated in 80% t can be recrystallized from anisole and melts 189°. Finally, on prolonged heating above

fourth equivalent of hydrogen is evolved, and VI can be isolated in 98% yield. It melts, after lization from ethanol, at 230–231°.

tructure of IV is consistent with the following: chiometry of hydrogen evolution, elemental the infrared spectrum which shows a strong tch multiplet resembling that of pyrazole at 60  $\text{cm}^{-1}$ , and the  $\text{H}^1$  nmr spectrum which shows e pyrazole hydrogens as doublets at  $\tau$  2.42 (3 cps) and 2.49 ( $J = 2.2$  cps) and a triplet at  $\tau = 2.0$  cps) in a 1:1:1 ratio. The signal arising  $\text{I}_2$  hydrogens is broad and cannot be discerned, number of boron-bonded hydrogens can be ed as two by integration in the  $\tau$  3–9 range.

nmr spectrum consists of a triplet ( $J = 96$  itered at +25.7 ppm.<sup>10</sup>

ure V was established in similar fashion. The tch appeared as a single peak at about 2470 The  $\text{H}^1$  nmr spectrum in  $\text{D}_2\text{O}$  showed three e to CH hydrogens as doublets at  $\tau$  2.43 ( $J =$  and 2.82 ( $J = 2.2$  cps) and a triplet at  $\tau$  3.85 :3 ratio. The BH hydrogen of intensity 1 was y integration over the range  $\tau$  3–9. The  $\text{B}^{11}$  ctrum had a doublet ( $J = 105$  cps) at +19.6

alt  $\text{KB(pz)}_4$  showed no BH band in the infrared l three nmr peaks (in  $\text{D}_2\text{O}$ ): doublets at  $\tau \sim 1.7$  cps) and 2.62 ( $J = 2.3$  cps) and an ill- triplet at  $\tau$  3.67 in a 1:1:1 ratio. The  $\text{B}^{11}$  nmr n consisted of a sharp singlet at +17.3 ppm.

roton nmr spectra of  $\text{H}_2\text{B(pz)}_2^-$ ,  $\text{HB(pz)}_3^-$ , and ions show that all the pyrazolyl residues in each identical. The triplet (resolvable into a set of ing doublets) was readily assigned to the 4-H. other hand, the data available were insufficient n the  $J_{2,2}$  and  $J_{1,8}$  doublets.<sup>11</sup> In a similar 1 pertaining to 1-acyl-substituted pyrazoles,

e  $\text{B}^{11}$  nmr spectra were determined at 19.2 Mc, and the chemi- ure referred to external trimethyl borate. e 3,5 splitting of  $\sim 0.6$  cps is not always discernible.

Williams<sup>12</sup> concluded, by unambiguously blocking the 5 position, that the 5-H appears at *lower* field and that it has the *higher* coupling constant of the two. The above conclusions were corroborated later and extended to 1-alkylpyrazoles by other authors.<sup>13</sup>

Since there was no basis to assume *a priori* that these conclusions could be equally well applied to poly-(1-pyrazolyl)borates, and especially since boron is known to change the appearance of signals arising from well-known groups in unpredictable fashion,<sup>14</sup> the problem of assigning the 3-H and 5-H doublets in poly(1-pyrazolyl)borate ions had to be solved independently.

The approach chosen entailed studying the effect of changing the solvent and/or cation on the chemical shifts in  $\text{M}[\text{H}_n\text{B(pz)}_4 - n]$  salts. It was assumed that in solvents where ionization is suppressed and ion-pairing or, in the extreme case, chelation<sup>15</sup> of the cation takes place, the environment of the "outer," 3-H, would change more significantly than that of the "inner," 5-H, and suitable changes in their chemical shifts would be observed. In order to separate the differential solvent effect from the over-all solvent effect, the position of the 4-H was used as an internal standard, and changes in the distance ( $\Delta_{2,2}$  and  $\Delta_{1,8}$ ) of the two doublets  $J_{2,2}$  and  $J_{1,8}$  from it were measured in cycles per second. It was established that in a given system  $\Delta_{2,2}$  and  $\Delta_{1,8}$  are relatively independent of concentration.

When  $\Delta_{2,2}$  and  $\Delta_{1,8}$  were measured in water for a series of  $\text{MB(pz)}_4$  salts ( $\text{M} = \text{Li}, \text{Na}, \text{K}, \text{Cs},$  and  $\text{Me}_4\text{N}$ ), values of  $62 \pm 1$  and  $82 \pm 1$  cps, respectively, were obtained, which is consistent with complete separation of the ions. The situation changed dramatically upon switching to acetone as solvent. There  $\Delta_{1,8}$  remained relatively constant at  $84 \pm 2$  cps, but  $\Delta_{2,2}$  proved to be strongly cation dependent, and values of 45 (Li), 55 (Na), 65 (K), 72 (Cs), and 76 cps ( $\text{Me}_4\text{N}$ ) were obtained. The same effect was observed in dimethylformamide and dimethyl sulfoxide. There  $\Delta_{1,8}$  varied over 6–7 cps in going from the Li to the  $\text{Me}_4\text{N}$  salt, while  $\Delta_{2,2}$  ranged over 30 and 38 cps, respectively.

A similar situation prevails in  $\text{M}[\text{HB(pz)}_3]$  salts. There, too,  $\Delta_{2,2}$  and  $\Delta_{1,8}$  are relatively invariant in water ( $65 \pm 2$  and  $83 \pm 2$  cps, respectively). On switching to acetone  $\Delta_{1,8}$  remains at  $84 \pm 2$  cps while  $\Delta_{2,2}$  is again cation dependent with values of 98 (Li), 97 (Na), 93 (K), 84 (Cs), and 80 cps ( $\text{Me}_4\text{N}$ ). This behavior is also noted in other solvents such as dimethylformamide, dimethyl sulfoxide, and acetonitrile, where  $\Delta_{1,8}$  remains relatively constant at  $83 \pm 3$  cps, while  $\Delta_{2,2}$  values range over 12–17 cps. Since in all of these cases the  $J_{2,2}$  doublet appears at either higher or lower field than the  $J_{1,8}$  doublet, the hazard involved in assigning the 3- and 5-hydrogens in unsymmetrical pyrazoles on the basis of their chemical shifts alone becomes immediately obvious.

If the cation is held constant but the solvent varied,

<sup>a</sup> Sublimed. <sup>b</sup> Recrystallized from heptane. <sup>c</sup> Recrystallized from toluene. <sup>d</sup> Ebullioscopic in benzene. <sup>e</sup> Ebullioscopic in methylene chloride.

the same behavior is observed. For instance, for  $LiHB(pz)_3$ ,  $\Delta_{1,8}$  is 84 and 86 cps in water and acetone, respectively, while the corresponding  $\Delta_{2,2}$  values are 64 and 98 cps. Intermediate values for  $\Delta_{2,2}$  may be obtained by using water–acetone mixtures as solvent. Analogous, if less dramatic, results were obtained with other cation or solvent combinations as well as with the  $M[H_2B(pz)_2]_2$  salts.

These results show clearly that the chemical shift of the  $J_{2,2}$  doublet is much more cation and solvent dependent than that of the  $J_{1,8}$  doublet. On this basis, the former is assigned to the 3-H and the latter to the 5-H.

When sodium or lithium borohydrides are used instead of potassium borohydride, the corresponding sodium and lithium poly(1-pyrazolyl)borates are obtained. It is noteworthy that  $LiHB(pz)_3$ ,  $LiB(pz)_4$ , and  $NaHB(pz)_3$  can be sublimed *in vacuo* without decomposition.

The oxidative and hydrolytic stability of poly(1-pyrazolyl)borates increases with decreasing number of hydrogens attached to boron. Thus,  $H_2B(pz)_2^-$  is oxidized instantaneously by aqueous permanganate,  $HB(pz)_3$  is oxidized slowly, while  $B(pz)_4^-$  remains unaffected under these conditions. This trend is also corroborated by polarographic studies. The same order of stability is observed with regard to storage of their solutions:  $B(pz)_4^-$  can be stored for long periods of time in solution without noticeable deterioration, while  $HB(pz)_3^-$  is stored less well, and  $H_2B(pz)_2^-$  solutions have to be used within a few days. In the solid state, however, all three salts can be stored for years at room temperature exposed to air and light.

Careful acidification of aqueous solutions of IV, V, and VI with acetic acid yields the corresponding free acids as water-insoluble solids. This is the first known instance of a stable free acid derived from a  $[BR_nR'_4-n]^-$  species being isolated,<sup>16</sup> and it underscores the importance of chelation as a stabilizing factor.

The exact structure of these free acids has not been determined. They may be ion pairs or have a "chelated proton" structure. They are hydrated to varying degrees. Analysis of the free acid derived from  $KH_2B(pz)_2$  fits best  $H[H_2B(pz)_2]_2 \cdot 4H_2O$ , which is in accord with

(16) The ions  $[BR_nR'_4-n]^-$  are extremely sensitive to aqueous acid: R. Damico, *J. Org. Chem.*, **29**, 1971 (1964). Even in the case of relatively stable  $B(C_6H_5)_4^-$ , no evidence for the existence of a viable  $HB(C_6H_5)_4$  species was found: J. H. Cooper and R. E. Powell, *J. Am. Chem. Soc.*, **85**, 1590 (1963). On the other hand, the preparation of  $H[(C_6H_5)_3B(OH)_2]$ , mp –35 to –33°, has been claimed: B. M. Mikhailov and V. A. Vaver, *Dokl. Akad. Nauk SSSR*, **102**, 531 (1955).

data pertaining to hydration of a proton extracted into organic solvents.<sup>17</sup> On the other hand,  $HB(pz)_3$  is essentially anhydrous. That these solids do indeed contain the intact  $[H_nB(pz)_4-n]^-$  ion is indicated by the fact that they can be reconverted to salts with the same or different cation by titration with an alkali or onium hydroxide. Moreover, the free acids do react readily with transition metal ions giving the same chelates as those obtained from the salts. In fact, precipitation of  $M[H_nB(pz)_4-n]_2$  chelates is often carried out advantageously slightly on the acid side to avoid coprecipitation of transition metal hydroxides. The free acid derived from  $KHB(pz)_3$  is the least stable of the three and could not be recrystallized. Nevertheless, it too could be converted to  $HB(pz)_3^-$  salts by titration with metal or onium hydroxides. All the free acids have infrared spectra generally similar to those of the salts from which they were derived. They all have broad absorption around 2000–3000  $cm^{-1}$ , and area characteristic of intramolecular hydrogen bonding.

Coordination compounds derived from  $H_2B(pz)_2^-$ ,  $HB(pz)_3^-$ ,  $B(pz)_4^-$ , and divalent first-row transition metal ions can be prepared readily by metathesis. Since the compounds  $M[H_2B(pz)_2]_2$  and  $M[HB(pz)_3]_2$  are of different structural types, they will be discussed separately.

Chelates of  $Mn^{2+}$ ,  $Fe^{2+}$ ,  $Co^{2+}$ ,  $Ni^{2+}$ ,  $Cu^{2+}$ , and  $Zn^{2+}$  are precipitated immediately when aqueous solutions of  $KH_2B(pz)_2$  and the appropriate metal ion are mixed. Similarly, the compounds  $M[H_2B(pz)_2]_2$  are precipitated when M is  $Pb^{2+}$  or  $Cd^{2+}$ , but not when M is  $Mg^{2+}$ ,  $Ca^{2+}$ ,  $Sr^{2+}$ , or  $Ba^{2+}$ .  $Ag^+$ ,  $Pd^{2+}$ , and  $Hg^{2+}$  ions are reduced to the free metals. Compounds  $M[H_2B(pz)_2]_2$  are extractable with organic solvents, particularly well with methylene chloride. They are stable to air and moisture and can be stored in the solid state for years without decomposition, with the exception of the unstable, air-sensitive  $Mn[H_2B(pz)_2]_2$  and  $Fe[H_2B(pz)_2]_2$ . Most of them can be sublimed *in vacuo*, although sublimation is at times accompanied by decomposition to diverse products, mainly metal pyrazolide, pyrazabole, and  $M[HB(pz)_3]_2$ . For this reason purification by recrystallization or by chromatography is preferred. Properties of  $M[H_2B(pz)_2]_2$  compounds are summarized in Table I. Their structures were determined as follows.

From *a priori* consideration of contributing structures of the  $H_2B(pz)_2^-$  ion, it is apparent that significant contributions are to be expected from structures VIIb and c.

(17) M. I. Tocher, D. C. Whitney, and R. M. Diamond, *J. Phys. Chem.*, **68**, 368 (1964), and references cited therein.

structures have electronic and geometric features: a negative charge and an available electron pair at the termini of the N-N-B-N-N sequence which can exchange places by way of resonance) similar to those of the anion derived from an imine 1,3-dicarbonyl compound or its imine.

Hence, as a first approximation, structures analogous to metal acetylacetonates would be expected. It should be noted, however, that (a) the 3-CH group is close to the metal atom, thus shielding it, especially in tetrahedral chelates, and (b) both nitrogen atoms in pyrazole are involved in bond formation or coordination and hence are expected to be unreactive. These reasons favor formation of associated species, such as dimers, encountered in various nickel(II) and cobalt(II) complexes,<sup>18</sup> would not be anticipated. Indeed, all  $M[H_2B(pz)_2]_2$  compounds show no evidence of self-association or planar-tetrahedral equilibrium and are monomeric.

Infrared spectra of  $Mn[H_2B(pz)_2]_2$ ,  $Fe[H_2B(pz)_2]_2$ ,  $Co[H_2B(pz)_2]_2$ ,  $Ni[H_2B(pz)_2]_2$ ,  $Cu[H_2B(pz)_2]_2$ , and  $Zn[H_2B(pz)_2]_2$  are all very similar. Closer examination of these spectra can be divided into two groups, the spectra within each group being identical. The first group (A) belong to  $Ni[H_2B(pz)_2]_2$  and  $Cu[H_2B(pz)_2]_2$ ; to the other (B),  $Mn[H_2B(pz)_2]_2$ ,  $Fe[H_2B(pz)_2]_2$ ,  $Co[H_2B(pz)_2]_2$ , and  $Zn[H_2B(pz)_2]_2$ . There are regions of the spectrum where differences are apparent.

(1) the fine structure in the  $BH_2$  stretch region (around 1060  $cm^{-1}$ ) where the second strongest band in group B is resolved into a doublet, compared with group A where the band around 1060  $cm^{-1}$  is a doublet in group A; and (3) the 850–950- $cm^{-1}$  region is distinctly different in each group.

Since the same ligand is involved in all these compounds, the differences in ionic radii of the metal ions are comparable, and the observed spectral differences are ascribed to differences in molecular geometry. Since zinc forms exclusively tetrahedral complexes, group B must consist of tetrahedral chelates while those of group A are expected to be square planar. In accord with this,  $Ni[H_2B(pz)_2]_2$  is orange-red and diamagnetic. The  $BH_2$  region in the infrared spectra of  $Ni[H_2B(pz)_2]_2$  and  $Cu[H_2B(pz)_2]_2$  is more similar to that of pyrazabole, which is consistent with molecular models which indicate a tetrahedral environment of the  $BH_2$  in the above compounds resembles that found in pyrazabole rather than in chelates from group B.

The nmr spectra of the diamagnetic chelates  $Ni[H_2B(pz)_2]_2$  and  $Zn[H_2B(pz)_2]_2$  each consisted of two singlets and a triplet (made up of two overlapping singlets) in a 1:1:1 ratio. They were at  $\tau$  2.38 ( $J = 1$ ), 3.17 (2.1), and 3.87 (2.1) for  $Ni[H_2B(pz)_2]_2$  and  $\tau$  2.29 ( $J = 2.3$  cps), 2.46 (2.3 cps), and 3.80

(2.3 cps) for  $Zn[H_2B(pz)_2]_2$  again implying fundamentally different molecular geometries.

Definitive evidence for the structure of all these chelates was obtained from magnetic data, electronic spectra, and nmr studies of the paramagnetic chelates.<sup>19</sup>

Figure 1. Infrared spectra of  $M[H_2B(pz)_2]_2$  compounds.

Compounds of structure  $M[HB(pz)_2]_2$  are precipitated immediately upon mixing solutions of an alkali or onium hydrotris(1-pyrazolyl)borate and of a divalent transition metal ion. In addition, such compounds are also precipitated with  $Mg^{2+}$ ,  $Pb^{2+}$ ,  $Cd^{2+}$ , and  $Pd^{2+}$  ions. Using  $Ag^+$  ion, the compound  $AgHB(pz)_2$  is obtained. The  $Ag$  as well as the  $Pd$  compounds decompose readily on heating with formation of the free metal. Besides  $Mg^{2+}$ ,  $Ca^{2+}$  is also precipitated by the  $HB(pz)_2^-$  ion but from more concentrated solutions. The solubility in water of alkaline earth hydrotris(1-polypyrazolyl)borates increases in the order  $Mg \ll Ca < Sr < Ba$ . The strontium and barium compounds are salt-like and, like the alkali salts, may serve as starting materials for the preparation of transition metal compounds. The calcium compound behaves in some ways like a salt and in others like a chelate, although  $Mg[HB(pz)_2]_2$  behaves like one of the transition metal compounds in terms of physical properties. Despite their high solubility in water,  $Sr[HB(pz)_2]_2$  and  $Ba[HB(pz)_2]_2$  can be extracted with organic solvents, e.g., methylene chloride, and  $Sr[HB(pz)_2]_2$  can be sublimed *in vacuo* without decomposition.

The transition metal compounds  $M[HB(pz)_2]_2$  are all high-melting solids, sublimable *in vacuo*. They are sparingly soluble in polar solvents such as alcohols or acetone but dissolve readily in halocarbons and aromatic hydrocarbons from which they may be conven-

<sup>a</sup> All samples were recrystallized from toluene. <sup>b</sup> By vapor-pressure osmometry in chloroform.

iently recrystallized. Some properties of  $M[HB(pz)_3]_2$  are summarized in Table II.

Nothing has been said thus far about the structure of these compounds. Since chelates  $M[H_2B(pz)_2]_2$  are, in terms of geometry and symmetry, similar to transition metal acetylacetonates or to the  $BR_2$ -bridged bis-(dimethylglyoxime)nickel(II)<sup>20</sup> and its cobalt analog,<sup>21</sup> one might expect a similar structure in  $M[HB(pz)_3]_2$  compounds except for the 1-pyrazolyl group replacing a hydrogen. That this is not the case became apparent.

For one thing, the colors of the iron, cobalt, nickel, and copper compounds are all different from those in the corresponding  $M[H_2B(pz)_2]_2$  compounds and essentially identical with those of the corresponding complexes with the isosteric and isoelectronic ligand, 1,1,1-tripyrzolylmethane.<sup>22</sup> Molecular models<sup>23</sup> show that the 2-nitrogen of the third pyrazolyl group is in such close proximity to the metal ion that it can form a coordinate bond with it, thus giving rise to a compact structure of  $D_{3d}$  symmetry.

Figure 2. Infrared spectra of  $M[HB(pz)_3]_2$  and  $M[B(pz)_4]_2$  compounds.

Compounds  $M[HB(pz)_3]_2$  have the simplest infrared spectra (Figure 2) among poly(1-pyrazolyl)borates, all containing a BH singlet.<sup>24</sup> The  $Cu[HB(pz)_3]_2$  is sig-

(22) S. Trofimenko, unpublished results.

(23) While the exact dimensions of the pyrazole ring are not known, the Stuart-Briegleb models provide a good qualitative picture of the molecular structure.

nificantly different in having several of the peaks that are singlets in other  $M[HB(pz)_3]_2$  compounds appear as doublets. The nmr spectra of  $M[HB(pz)_3]_2$  compounds discern only one kind of pyrazolyl group. The octahedral nature of these compounds is also confirmed by electronic spectra, magnetic data, and nmr studies of paramagnetic compounds.<sup>19</sup> An interesting case of spin equilibrium between high- and low-spin forms has been found in  $Fe[HB(pz)_3]_2$ .<sup>25</sup>

Compounds  $M[B(pz)_4]_2$ , which have the same octahedrally coordinated structure around the metal ion as  $M[HB(pz)_3]_2$ , are, nevertheless, in some ways different. They are prepared by metathesis and have the same colors as their  $M[HB(pz)_3]_2$  counterparts. They, too, are sublimable but are higher melting, more thermally stable, and less soluble in organic solvents. However, the presence of two additional 1-pyrazolyl groups per molecule makes  $M[B(pz)_4]_2$  compounds soluble in aqueous mineral acids from which they can be recovered on basification. In addition to divalent first-row transition metal ions,  $Cd^{2+}$ ,  $Pd^{2+}$ ,  $Hg^{2+}$ , and  $Ag^+$  are precipitated, and of these all but the silver compound can be purified by recrystallization. In the alkaline earth group  $Mg^{2+}$  is precipitated readily,  $Ca^{2+}$  less readily, and  $Sr^{2+}$  and  $Ba^{2+}$  are too soluble to be precipitated except from very concentrated solutions. The infrared spectra of all  $M[B(pz)_4]_2$  compounds are similar (Figure 2) and devoid of BH absorption. Their properties are shown in Table III.

Convincing proof that one of the four 1-pyrazolyl groups attached to boron is different from the other three is provided by the nmr spectrum of the paramagnetic  $Co[B(pz)_4]_2$  compound where protons due to three identical and one different 1-pyrazolyl groups per ligand are discerned, the signals covering a range of over 12,000 cycles due to spin-contact interactions.<sup>19</sup>

At this point it is pertinent to touch on the mechanism of the reaction of pyrazole with the tetrahedral borohydride ion. While some work has been done in the area of displacement reactions on tetrahedral boron,<sup>26</sup> mainly relating to solvolytic and displacement reactions of borane complexes, the situation is by no means as clear as in the case of substitution on carbon.

(24) At higher resolution this is seen to consist of two peaks at 2460 and 2474  $cm^{-1}$  assigned, on the basis of their intensities, to the BH stretch of the  $B^{11}$  and  $B^{10}$  isotopes.

<sup>a</sup> Recrystallized from toluene. <sup>b</sup> Sublimed. <sup>c</sup> Recrystallized from water. <sup>d</sup> Calculated for dihydrate: C, 39.4; H, 3.82; N, 30.6. <sup>e</sup> Bullioscopic in toluene. <sup>f</sup> Osmometric in chloroform.

In our case, the reaction of borohydride ion with pyrazole is thought to proceed in a manner that combines some features of SN1 and SN2 reactions. This mechanism is probably also operating in the reaction of trimethylamine borane with pyrazole.

The main feature of this mechanism is a cyclic low-energy transition state with a geometry resembling that in SN2 substitution. However, while in SN2 actions the departing and the attacking groups are at the apices of a trigonal bipyramid, in the case of pyrazole and borohydride ion the evolution of hydrogen proceeds concertedly through a cyclic five-center transition state<sup>27</sup> and involves equatorial rather than apical

pyrazole, present in large excess, to yield the free acid  $H[H_2B(pz)_2]$  directly. This acid, in a basic medium, would be converted to the  $[H_2B(pz)_2]^-$  ion, as the potassium chelate. It should be noted that there is no noticeable break in hydrogen evolution until two pyrazole molecules per  $BH_4^-$  have reacted. The third pyrazolyl group is attached less readily, probably for steric reasons, and also because of possible orientation of the noncoordinating nitrogen in the transition state toward the potassium ion rather than toward the hydrogen to be eliminated.

The fourth pyrazolyl group is introduced very slowly as, by now, the access to the boron atom is quite obstructed. Possibly, a direct SN1 dissociation may occur with the slow step being followed by rapid reac-

tion of IX with pyrazole or pyrazolide ion.

When potassium borohydride is heated in excess 1,2,4-triazole, the hydrotris(1,2,4-triazol-1-yl)borate ion is formed, as proved by the formation of compound X when the reaction product was treated with  $Co^{2+}$  ion. This compound is yellow just like  $Co[HB(pz)_3]_2$ . In contrast to  $Co[HB(pz)_3]_2$ , however, it is soluble in and can be recrystallized from water. This solubility is attributable to the presence of six additional nitrogens in the molecule.

## Experimental Section

**Potassium Dihydrobis(1-pyrazolyl)borate.** Potassium borohydride (54 g, 1 mole) was mixed with 272 g (4 moles) of pyrazole in a 1-l. flask attached through an air condenser to a gas meter. The pyrazole was carefully melted by means of an oil bath at 90°. When the contents of the flask was sufficiently molten to allow magnetic stirring, the mixture was stirred and heated at tempera-

hydrogen. Here, both B-N bond forming and B-H

and breaking are facilitated by the "push-pull" effect of pyrazole approaching as a 1,3 dipole. The intermediate III could then again undergo the same type of reaction to reach a resonance-stabilized form as the potassium borohydride IV. Alternatively, the same stage could be reached by coordination of 1-dihydroborylpyrazole (obtained from VIII via loss of hydride ion) with

(27) This cyclic five-center transition state is probably characteristic of all pyrazole reactions with dipolarophiles AB; it is just as applicable e.g., acylation of pyrazoles as to hydrolysis of acylpyrazoles.

tures not exceeding 115°. Potassium borohydride dissolved slowly with evolution of hydrogen, and the progress of the reaction was followed on the gas meter. After 20 hr, 2 moles (ca. 50 l.) of hydrogen had evolved and only a few small particles of  $\text{KBH}_4$  were still floating in the melt. These were removed mechanically. The melt was poured into 500 ml of toluene; the resulting mixture was stirred until it cooled to room temperature and was then filtered. The filter cake was washed twice with 150-ml portions of hot toluene and then air-dried, yielding 137 g (74%) of a solid, mp 171–172°. The analytical sample was recrystallized from anisole. The infrared spectrum of the product has a complex BH pattern at 2250–2420  $\text{cm}^{-1}$ . *Anal.* Calcd for  $\text{C}_5\text{H}_5\text{BN}_2\text{K}$ : C, 38.7; H, 4.30; N, 30.1. Found: C, 38.9; H, 4.36; N, 29.9.

**Potassium Hydrotris(1-pyrazolyl)borate.** A mixture of 272 g (4.0 moles) of pyrazole and 54 g (1.0 mole) of potassium borohydride was heated with stirring in a 1-l. flask, connected *via* an air-cooled condenser to a gas meter, until about 75 l. (3 moles) of hydrogen had been evolved. The melt was poured slowly into 600 ml of stirred toluene, whereupon a solid precipitated. The mixture was filtered and the product was washed with hot toluene, then with hexane, and air-dried. There was obtained 190 g (79%) of white solid, mp 185–190°. The solid was recrystallized from anisole and obtained as fine needles, mp 188–189°. *Anal.* Calcd for  $\text{C}_5\text{H}_5\text{BN}_2\text{K}$ : C, 42.8; H, 3.97; N, 33.3. Found: C, 42.9; H, 4.23; N, 33.4.

**Lithium Hydrotris(1-pyrazolyl)borate.** This compound was prepared by the above method and obtained, after recrystallization from toluene, as needles, mp 264–265°. It is readily sublimable at 240° (2 mm). *Anal.* Calcd for  $\text{C}_5\text{H}_5\text{BLiN}_2$ : C, 49.1; H, 4.55; N, 38.2. Found: C, 48.8; H, 4.84; N, 38.2. This lithium salt is very soluble in water, acetone, alcohols, and tetrahydrofuran, moderately soluble in chloroform, and sparingly soluble in cold toluene.

**Sodium Hydrotris(1-pyrazolyl)borate.** This compound was prepared by the above method and obtained in 91% yield. It was purified by recrystallization from 1,2-dimethoxyethane and then by sublimation at 210–215° (2 mm), mp 222–223°. *Anal.* Calcd for  $\text{C}_5\text{H}_5\text{BN}_2\text{Na}$ : C, 45.7; H, 4.24; N, 35.5. Found: C, 45.5; H, 4.26; N, 35.2.

**Potassium Tetrakis(1-pyrazolyl)borate.** Potassium borohydride (54 g, 1 mole) and pyrazole (340 g, 5 moles) were heated together until about 100 l. of hydrogen (4 moles) was evolved. The melt was cooled until it became viscous and then was poured into 1.5 l. of stirred toluene. The mixture was filtered and the cake washed with successive portions of hot toluene, benzene, and ether. The solid was air-dried to give 310 g (98% yield). The analytical sample was recrystallized from ethanol and dried at 130° (2 mm), mp 253–254. *Anal.* Calcd for  $\text{C}_{12}\text{H}_{12}\text{BKN}_4$ : C, 45.3; H, 3.78; N, 35.2. Found: C, 45.1; H, 3.79; N, 35.2.

**Preparation of Poly(1-pyrazolyl)borate Salts by Neutralization of the Free Acids. General Procedure.** The free acids were prepared by adding an equimolar amount of acetic acid to a fairly concentrated aqueous solution of the appropriate potassium poly(1-pyrazolyl)borate. The precipitated free acid was isolated by filtration and washed thoroughly with water. It was then stirred with a stoichiometric amount of the appropriate alkali metal or quaternary ammonium hydroxide with additional methanol, as necessary, to effect homogeneity. The solutions were decolorized with Darco and evaporated at reduced pressure. The solid residues were recrystallized from an appropriate solvent, usually with substantial solubility losses.

**Tetramethylammonium Tetrakis(1-pyrazolyl)borate.** This compound was recrystallized from 1,2-dimethoxyethane and obtained in 93% yield. It decomposes with evolution of trimethylamine at 219–220°. *Anal.* Calcd for  $\text{C}_{14}\text{H}_{14}\text{BN}_6$ : C, 54.4; H, 6.81; N, 35.7. Found: C, 54.4; H, 7.02; N, 36.0. The nmr spectrum ( $\text{D}_2\text{O}$ ) has doublets at  $\tau$  2.33 ( $J < 2.0$  cps) and 2.62 ( $\sim 2.3$ ), a triplet at 3.67 ( $\sim 1.9$ ), and a singlet at 6.92 in exactly a 1:1:1:3 ratio.

**Lithium Tetrakis(1-pyrazolyl)borate.** This compound was obtained in 89% yield and was recrystallized from water. It was purified further by sublimation at 300° (2 mm), mp 394–395°. *Anal.* Calcd for  $\text{C}_{12}\text{H}_{12}\text{BLiN}_4$ : C, 50.3; H, 4.19; N, 39.2. Found: C, 50.3; H, 4.36; N, 38.8. The nmr ( $\text{D}_2\text{O}$ ) has an unresolved doublet at  $\tau$  2.26, a doublet ( $J \sim 2.2$  cps) at  $\tau$  2.58, and an unresolved triplet at  $\tau$  3.60 in a 1:1:1 ratio.

**Sodium Tetrakis(1-pyrazolyl)borate.** This compound was obtained in 80% yield after recrystallization from ethanol, mp 238–239°. *Anal.* Calcd for  $\text{C}_{12}\text{H}_{12}\text{N}_4\text{BNa}$ : C, 47.7; H, 3.97; N, 37.1. Found: C, 47.0; H, 3.87; N, 36.3.

**Cesium Tetrakis(1-pyrazolyl)borate.** This salt was obtained in 47% yield after recrystallization from ethanol, mp 243–244°. *Anal.* Calcd for  $\text{C}_{12}\text{H}_{12}\text{BCsN}_4$ : C, 35.0; H, 2.92; N, 27.2. Found: C, 34.9; H, 2.85; N, 26.6.

**Tetramethylammonium Dihydrobis(1-pyrazolyl)borate.** This salt was obtained in 58% yield after recrystallization from 1,2-dimethoxyethane, mp 107–108°. *Anal.* Calcd for  $\text{C}_{10}\text{H}_{10}\text{BN}_4$ : C, 54.2; H, 9.05; N, 31.7. Found: C, 54.0; H, 9.44; N, 31.3.

**Tetramethylammonium Hydrotris(1-pyrazolyl)borate.** This compound was obtained in 46% yield after recrystallization from 1,2-dimethoxyethane, mp 96–97°. *Anal.* Calcd for  $\text{C}_{13}\text{H}_{12}\text{BN}_5$ : C, 54.4; H, 7.67; N, 34.1. Found: C, 53.9; H, 7.38; N, 33.5.

**Hydrogen Dihydrobis(1-pyrazolyl)borate.** To a solution of 19 g (0.1 mole) of  $\text{KH}_2\text{B(pz)}_2$  in 200 ml of water was added 6.0 g (0.1 mole) of acetic acid. The precipitated solid was filtered, washed with water, and obtained, after air-drying, in 15.3-g yield.

Recrystallization from chloroform gave white crystals, mp 128–129°, with gas evolution. *Anal.* Calcd for  $\text{C}_6\text{H}_8\text{BN}_4$  (anhydrous acid): C, 48.7; H, 6.08; N, 37.9. Calcd for  $\text{C}_6\text{H}_{10}\text{BN}_4\text{O}_4$  (tetrahydrate): C, 32.7; H, 7.73; N, 25.5. Found: C, 33.6; H, 5.95; N, 25.5. The infrared spectrum of this material had, apart from the complex BH<sub>3</sub> sketch, broad and intense absorption characteristic of intramolecular hydrogen bonding at 1700–3000  $\text{cm}^{-1}$ .

**Hydrogen Hydrotris(1-pyrazolyl)borate.** This compound was prepared as above and obtained as a solid which decomposed on attempted recrystallization.

**Hydrogen Tetrakis(1-pyrazolyl)borate.** To a stirred solution of 159 g (0.5 mole) of potassium tetrakis(1-pyrazolyl)borate in 1 l. of water was added 30 g (0.5 mole) of acetic acid. The precipitated solid was separated by filtration, washed thoroughly with water and then ethanol, and air-dried overnight. It was purified further by dissolution in a minimum amount of methylene chloride and concentration under reduced pressure at 30–35° to a thick slurry. It was stirred with 500 ml of ether and filtered, and the solid was dried in a stream of warm nitrogen. There was obtained 27 g of material, mp 70–71°. *Anal.* Calcd for  $\text{C}_{12}\text{H}_{12}\text{BN}_4$ : C, 51.4; H, 4.64; N, 40.0. Found: C, 52.1; H, 4.69; N, 40.4.

**Preparation of Metal Dihydrobis(1-pyrazolyl)borates.** Compounds of this type were prepared by adding an aqueous solution of 1 equiv of the appropriate metal ion to an aqueous solution of 2 equiv of potassium dihydrobis(1-pyrazolyl)borate. The chelates precipitated immediately. In the case of the air-sensitive chelates of Mn(II) and Fe(II), the addition and subsequent manipulations had to be done in an inert atmosphere. The products were isolated either by filtration or by extraction with methylene chloride. While they could be sublimed with care, such sublimation was at times attended by pyrolysis to metal pyrazolide and pyrazabole, hence recrystallization from toluene or heptane was preferred. The properties of metal dihydrobis(1-pyrazolyl)borates are summarized in Table I.

**Preparation of Metal Hydrotris(1-pyrazolyl)borates.** Compounds of this type were prepared by adding a solution of 1 equiv of the appropriate metal ion to a stirred solution of 2 equiv of potassium hydrotris(1-pyrazolyl)borate. The precipitated product was either extracted with methylene chloride or filtered and purified further by recrystallization from xylene and/or sublimation. Some products were purified by chromatography on acid-washed alumina. The properties of metal hydrotris(1-pyrazolyl)borates are listed in Table II.

**Preparation of Metal Tetrakis(1-pyrazolyl)borates.** These compounds were prepared as described above. Metal tetrakis(1-pyrazolyl)borates were, as a rule, less soluble than the tris analogs; hence, filtration was preferred to extraction. The properties of metal tetrakis(1-pyrazolyl)borates are summarized in Table III.

**Hydrotris(1,2,4-triazol-1-yl)boratecobalt(II).** A mixture of 5.4 g of potassium borohydride and 27 g of 1,2,4-triazole (0.1 and 0.4 mole, respectively) was heated until 7.5 l. (0.3 mole) of hydrogen was evolved. The melt was dissolved in 800 ml of hot water (90°) and was treated with 100 ml of 0.5 M cobaltous acetate solution. A precipitate formed which was insoluble in methylene chloride and was recrystallized from 800 ml of boiling water to give 3.9 g (16% yield) of well-shaped yellow crystals. The material darkens from 390° up but is still solid at 450°. *Anal.* Calcd for  $\text{C}_3\text{H}_3\text{BCoN}_3$ : C, 29.3; H, 2.85; N, 51.3. Found: C, 29.5; H, 2.93; N, 51.4.

**Polarographic Studies.** All the samples were dissolved in acetonitrile, except for the iron compounds which were dissolved in dimethyl sulfoxide. The solutions were 0.1 M in tetrabutylammonium perchlorate, used as supporting electrolyte. The dropping mercury electrode *vs.* sec was used with  $\text{Cu}(\text{H}_2\text{B(pz)}_2)_2$ ,  $\text{CuB}$

(pz)<sub>3</sub>, Co(H<sub>2</sub>B(pz)<sub>3</sub>), and Co[HB(pz)<sub>3</sub>]. The rotating platinum electrode *vs.* sce was used for Fe[HB(pz)<sub>3</sub>] and Fe[B(pz)<sub>3</sub>].

Both Cu[H<sub>2</sub>B(pz)<sub>3</sub>] and Cu[B(pz)<sub>3</sub>] were found to undergo reversible one-electron reduction at about  $E_{1/2} = 0.29$  v. The cobalt compounds, Co(H<sub>2</sub>B(pz)<sub>3</sub>) and Co[HB(pz)<sub>3</sub>], were oxidized (one electron) at +0.2 and -0.09 v, respectively. Co[HB(pz)<sub>3</sub>] underwent a two-electron reduction at -2.13 v, while its Fe(II)

counterpart could not be reduced in the +0.34- to -2.75-v range. Fe[HB(pz)<sub>3</sub>] and Fe[B(pz)<sub>3</sub>] underwent one-electron oxidation at +0.27 and 0.37 v, respectively.

**Acknowledgment.** The author wishes to thank Miss Lucille E. Williams who carried out the polarographic studies.

## Cyanonitrene. Reaction with Saturated Hydrocarbons<sup>1</sup>

A. G. Anastassiou<sup>2</sup> and H. E. Simmons

*Contribution No. 1288 from the Central Research Department, Experimental Station, E. I. du Pont de Nemours and Company, Wilmington, Delaware 19898.*

*Received February 4, 1967*

**Abstract:** Cyanonitrene was generated thermally from cyanogen azide, and its intermediacy in reactions with saturated hydrocarbons was established by means of isotopic labeling. The nitrene exhibits pronounced selectivity in insertions into C-H bonds, which in the absence of a solvent occur in a stereospecific manner. Mechanisms are discussed.

In contrast to the well-documented chemistry of carbenes,<sup>3</sup> their nitrogen counterparts (nitrenes)<sup>4</sup> have received serious attention by organic chemists only recently.<sup>5</sup> In 1962, Barton and Morgan<sup>6</sup> reported the first examples of intramolecular C-H insertions<sup>7</sup> of alkyl nitrenes to afford either five- or three-membered rings, and Lwowski and Mattingly<sup>8</sup> presented the first case of an intermolecular insertion<sup>7</sup> in the reaction of carbethoxynitrene with cyclohexane.

The recent synthesis of cyanogen azide (N<sub>3</sub>CN)<sup>9</sup> has provided a direct route for the generation of the highly symmetrical molecule NCN, "cyanonitrene." In the present paper we report on the thermal generation of NCN and on the mechanism of its reactions with saturated hydrocarbons.

### Results and Discussion

Unlike most organic azides which require temperatures in excess of 100° for fragmentation to the corresponding nitrenes,<sup>4</sup> cyanogen azide smoothly evolves nitrogen when heated to 40–50°. Kinetics have not been studied in detail but the rate of nitrogen evolution appears to be first order in dilute solutions. In addition the rate of nitrogen evolution depends on the polarity of the solvent employed, being more rapid in nonpolar media (hydrocarbons) than in polar media (ethyl acetate, acetonitrile). These facts are consistent

with unimolecular fragmentation of the highly polar azide to two nonpolar species. When the decomposition of the azide is conducted in a paraffinic hydrocarbon, alkylcyanamides **1** are formed in yields of 55–70%.

For example, thermolysis of a 1% solution of N<sub>3</sub>CN<sup>10</sup> in cyclohexane at 50° afforded cyclohexylcyanamide (**1**, R = C<sub>6</sub>H<sub>11</sub>) in 57% yield. The product showed strong infrared absorption at 3200 (NH) and 2210 (C≡N) and nmr signals at  $\tau$  4.3 (doublet, 1 H), 7.0 (multiplet, 1 H), and 7.9–9.0 (multiplet, 10 H); cyclohexylcyanamide was characterized by hydrolysis to cyclohexylurea on boiling with 10% sulfuric acid.

**Isotopic Labeling Experiments.** In photolytic or thermolytic reactions of azides with saturated hydrocarbons to yield insertion products, a likely mechanism involves unimolecular fragmentation of the azide to the corresponding nitrene and nitrogen followed by insertion<sup>7</sup> of the nitrene into C-H bonds. Although this is the most reasonable sequence of events, there usually is no unequivocal experimental evidence excluding an alternative mechanism in which the azide itself reacts with the hydrocarbon. The two possible mechanisms are depicted in Scheme I.<sup>11</sup>

Scheme I

(10) This experiment was first carried out by Dr. F. D. Marsh.

(11) In Scheme Ib the dipolar intermediate is supposed to be associated with singlet N<sub>2</sub>CN and the diradical species with triplet N<sub>2</sub>CN. Thus, abstraction of hydrogen might occur as either hydride ion or as a hydrogen atom.

(1) This work was described in preliminary form: A. G. Anastassiou, H. E. Simmons, and F. D. Marsh, *J. Am. Chem. Soc.*, **87**, 2296 (1965).

An unambiguous distinction between paths a and b should be possible in principle by isotopic labeling experiments. Theory suggests that the lowest singlet and triplet states of NCN are linear. Symmetry demands that the two nitrogen atoms of NCN are equivalent, whereas no such equivalence can be achieved in path b. To elucidate this point we studied the insertion reaction employing appropriately labeled  $N_3CN$ .

The procedure used is shown in Scheme II. The degree of isotopic enrichment at the various stages was

Scheme II

determined mass spectrometrically employing the natural abundances of the same materials prepared in parallel experiments but starting with unenriched potassium azide. The results of these experiments are clearly consistent with the intermediacy of *free* cyanonitrene in which the two nitrogen atoms are chemically indistinguishable.<sup>12</sup> The possibility that scrambling of the label occurs prior to decomposition of the azide, perhaps through a rapid prereaction equilibrium between a cyclic form 4 and two equivalent but differently tagged linear forms of  $N_3CN$ , was tested by allowing the azide to decompose partially in acetonitrile and then adding norbornene.<sup>9</sup> The virtual identity of the amount of label in 5 and its subsequent hydrolysis product 6 pre-

(12) The small excess label in amines 2 and 3 (28.7%  $^{15}\text{N}$  instead of the theoretical value of 25.0%) is probably at least partly due to an isotopic bias of the insertion, i.e., a slight preference of the  $^{15}\text{N}$  site over the  $^{14}\text{N}$  site of NCN to undergo reaction.

cludes the occurrence of any significant prereaction scrambling.

**Electronic Structure of NCN.** Cyanonitrene has ten bonding electrons. Simple valence theory predicts the lowest energy electronic configuration for cylindrically symmetrical NCN to be  $\dots 2\sigma_g^2 2\sigma_u^2 1\pi_u^4 1\pi_g^2$ , where  $\pi_g^2$  could be  $\pi_g^2(x)$ ,  $\pi_g^2(y)$ , or  $\pi_g^1(x)\pi_g^1(y)$ . Therefore, we have a situation where two electrons have to be distributed among two degenerate molecular orbitals. According to multiplet theory such an arrangement should give rise to one triplet and three singlet states:  $^3\Sigma_g^-, ^1\Sigma_g^+, [\dots \pi_g^1(x)\pi_g^1(y)]$ ; and two  $^1\Delta_g [\dots \pi_g^2(x)$  and  $\dots \pi_g^2(y)]$ . Electron repulsion considerations suggest that the triplet should be lowest in energy and hence represent the ground state.

Theory was verified by a number of recent spectroscopic studies involving flash photolysis,<sup>13,14</sup> electron paramagnetic resonance,<sup>15</sup> and matrix isolation<sup>16</sup> experiments. The results of all these investigations point strongly to  $^3\Sigma_g^-$  as the ground state. Support for this conclusion was also provided recently by flash photolysis experiments in which  $N_3CN$  was photolyzed in the absence of an inert gas diluent.<sup>17</sup> Under these conditions the originally observed species was the  $^1\Delta_g$  singlet which decayed to  $^3\Sigma_g^-$  at a measurable rate. Further information concerning the structure of NCN derives from a vibrational analysis<sup>18</sup> of its ultraviolet spectrum which afforded a carbon-nitrogen distance very close to that of a C=N bond, suggesting structure 7 as a good representation for the ground state.

**Selectivity of the Insertion Reaction.** The mild conditions employed in the present work for the generation of NCN suggest that it is produced in a low-energy electronic state. It is reasonable to assume that reacting NCN would be in the lowest electronic state of a given multiplicity, since radiationless decay is usually extremely rapid compared to diffusion. Hence, only the  $^3\Sigma_g^-, ^1\Sigma_g^+$ , and  $^1\Delta_g$  states need concern us here. For these low-lying states the three distinct modes of reaction shown in Scheme III are formally possible.<sup>11</sup>

Scheme III

(13) G. Herzberg and D. N. Travis, *Can. J. Phys.*, **42**, 1658 (1964).

(17) H. W. Kroto, *ibid.*, **44**, 831 (1966).

(18) This is correct only for the low-energy states considered here in which the reactive electrons are roughly isoenergetic. In higher excited electronic states the distinction between singlets and triplets is

Of these, (a) and (c) represent the commonly considered one-step and two-step mechanisms for singlet and triplet species, respectively. Path b becomes a distinct possibility only with highly electrophilic species such as NCN which possess a vacant low-energy bonding MO, e.g.,  $\pi^*$ , of  $^1\Delta_g$ .

To obtain information about the mechanism of the insertion, we determined the selectivity of the reaction with various types of C-H links both in intramolecular and intermolecular competition experiments. In the intramolecular competition experiments,  $N_2CN$  was thermolyzed at  $46.1^\circ$  in neat *n*-hexane, 2,3-dimethylbutane, and 2,2-dimethylbutane to afford the corresponding alkylcyanamides in the yields and relative amounts indicated in Scheme IV. The proportions of the various products were determined from the nmr spectra of the crude mixtures (see Product Analysis).

Scheme IV

The product distributions in Scheme IV are given as relative rates in Table I (A). The pronounced selectivity of NCN indicated by these results suggests that

appreciable C-H bond rupture occurs in the transition state, but does not provide any relevant information concerning the details of the bond-breaking process which could enable us to decide among the possible reaction

reactions does not appear to be as well defined. For a discussion of this point see A. G. Anastassiou, *J. Am. Chem. Soc.*, **89**, 3184 (1967).

paths. Of the three rate-limiting transition states shown in brackets in Scheme III, only (b) closely resembles that of an  $S_N1$  process with hydride ion partly bound to NCN acting as the leaving group. At first glance it appears that the discrimination of NCN for the various types of hydrogen is far too low for such a process.<sup>19</sup> However, this comparison is not strictly correct, since we may be witnessing a duality of mechanism akin to that observed in solvolytic displacements. For example, singlet NCN could be reacting by path a with primary C-H bonds, by path b with tertiary C-H bonds, and by a combination of paths a and b with secondary C-H bonds. Therefore, in order to distinguish among the three possible alternatives, it was necessary to devise additional experiments. It is known that in saturated carbocycles the rate of formation of an incipient carbonium ion is a sensitive function of ring size. For example, cyclooctyl tosylate and cycloheptyl tosylate solvolyze, respectively, >286 and 31 times as rapidly as cyclohexyl tosylate, which in turn is roughly as reactive as isopropyl tosylate.<sup>20</sup> These rate differences are commonly attributed<sup>20</sup> to the required hybridization changes involved in the incipient formation of carbonium ions, which occur more readily in the cyclooctyl and cycloheptyl systems than in the cyclohexyl system. This information coupled with the fact that of the three mechanisms in Scheme III only (b) requires any drastic hybridization changes<sup>21</sup> suggested that a determination of the relative ease with which NCN reacts with the C-H bonds of various cycloalkanes may provide significant information concerning the occurrence or absence of mechanism b. Furthermore, the comparison of the results ought to be free of the ambiguity introduced by a possible duality of mechanism since the C-H bonds involved are all of the same type.

We have carried out intermolecular competition experiments and have found virtually no difference in reactivity among the methylene hydrogens of *n*-hexane, cyclohexane, cycloheptane, and cyclooctane. The results are collected in Table I (B). We interpret the observed lack of discrimination of NCN for the methylene groups of the three monocycles to mean that, at least in the absence of a solvent, secondary and certainly the less reactive primary C-H bonds do not react by a hydride-abstraction process such as that indicated in Scheme IIIb. These experiments do not, of course, provide any information concerning the mode of reaction of tertiary C-H bonds. Hydride abstraction here should be more favorable than with the other types of C-H bonds because of the production of a more stable tertiary cation.

Additional support for the nonoccurrence of mechanism b was obtained in the following manner. If an ion pair is produced, the carbonium ion might be amenable to skeletal rearrangement if it is of appropriate structure. Carbonium ion 8 is particularly susceptible to skeletal reorganization to ion 9, e.g., both

(19) Larger rate differences are usually observed in  $S_N1$  processes. For example, *t*-butyl bromide solvolyzes ca.  $10^7$  times as fast as isopropyl bromide: L. C. Bateman and E. D. Hughes, *J. Chem. Soc.*, 945 (1940).

(20) A. Streitwieser, Jr., "Solvolytic Displacement Reactions," McGraw-Hill Book Co., Inc., New York, N. Y., 1962, p 95.

(21) This statement rests on the assumption that (1) little rehybridization is necessary in the three-center process a, and (2) the commonly accepted view that alkyl radicals are not subject to any stringent hybridization requirements.

oxidative decarboxylation<sup>22</sup> of acid **10** ( $X = \text{COOH}$ ) and nitrous acid deamination of the corresponding amine **10**, ( $X = \text{NH}_2$ )<sup>23</sup> yield **11** as the major product and material with intact skeleton is not produced (Scheme V). In the present work, cyanogen azide was thermolyzed in 1,1-dimethylcyclohexane and the crude cyanamide mixture was converted to the corresponding amino and methylamino compounds with excess lithium hydride. Gas-liquid partition chromatographic (glpc) analysis established the absence ( $<2\%$ ) of the amines **11** ( $Y = \text{NH}_2, \text{NHCH}_3$ ).<sup>24, 25</sup>

Scheme V

**Stereochemistry of the Insertion Reaction.** In principle, the direct insertion mechanism (a) and that involving hydrogen abstraction-recombination (b) ought to be distinguishable stereochemically. Path a is expected to be stereospecific leading to over-all retention of configuration, whereas path b should generate the products in a stereochemically random fashion under some conditions. In order to distinguish between these two mechanisms, we examined the stereochemical course of the insertion reaction. We employed the stereoisomeric 1,2-dimethylcyclohexanes as paraffinic substrates because of their ready availability in high purity and because the key products, 1-amino- and 1-methylamino-1,2-dimethylcyclohexane, are known in both stereoisomeric (but unassigned) forms. The results of these experiments are depicted in Scheme VI and tabulated in Table II.

Scheme VI

(22) C. Walling, "Molecular Rearrangements," Part 1, P. de Mayo, Ed., Interscience Publishers, Inc., New York, N. Y., 1963, p 421.

(23) R. Kotani, *J. Org. Chem.*, **30**, 350 (1965).

(24) Authentic materials were synthesized according to R. Jacquier and H. Christol, *Bull. Soc. Chim. France*, 596 (1957).

(25) The selectivity values shown in Table I suggest that ca. 6% of the product should arise from attack on primary C-H which, in the event that a carbonium ion is an intermediate, should mostly afford **11** ( $Y = \text{NHCH}_3$ ). The amount of **11** expected is well above the detection limits of our glpc analysis.

**Table II.** Stereochemistry of the Insertion Reaction of Cyanonitrene into the Tertiary C-H Bonds of *cis*- and *trans*-1,2-Dimethylcyclohexane

Hydrocarbon	Temp, °C	Products, %	
		<i>trans</i> -RNHCN (12)	<i>cis</i> -RNHCN (13)
<i>trans</i>	46.1	>98	<2
<i>cis</i>	46.1	<2	>98

It is seen that the reaction is highly stereospecific, each isomeric substrate producing a single ( $>98\%$ ) stereoisomeric cyanamide which was identified in each case by analysis of the configurationally homogeneous mixture of 1-amino- and 1-methylamino-1,2-dimethylcyclohexane (**14a,b** and **15a,b**). These products were assigned the indicated stereochemistry on mechanistic grounds, since the absolute stereochemistry of the known isomers has not yet been determined. It should be noted that a reversal of these assignments would imply that stereospecific insertion occurs with net inversion of configuration, which we consider unlikely. The assignments are also consistent with the glpc data which show that the more sterically hindered *cis* isomers have higher retention times. Irrespective of the specific assignments, the observed stereospecificity is consistent with a one-step insertion process and militates against any two-step processes such as those depicted in (b) and (c), which could lead to stereospecific product formation only in the unlikely event that recombination of the intermediate ion or radical pair occurs prior to inversion of the asymmetric center.

To obtain some information concerning this latter point, we have examined the stereochemical fate of the tertiary 1,2-dimethylcyclohexane radical generated in the liquid-phase, free-radical nitration<sup>26</sup> of *cis*-1,2-dimethylcyclohexane with 50% nitric acid. The amine mixture obtained by reduction of the originally produced nitro compounds consisted of 28% of a 1:1 *cis-trans* mixture of 1-amino-1,2-dimethylcyclohexane. This is in keeping with the anticipated configurational instability of the hydrocarbon radical.

**Product Analysis.** In the intramolecular competition experiments, cyanogen azide was thermolyzed in the various hydrocarbon substrates to yield mixtures of cyanamides. The constitutions of the *crude* mixtures were determined from the nmr spectra (neat). Under these conditions the N-H proton appears at  $\tau \sim 4.2$  and is quite sharp, exhibiting splitting consistent with the number of hydrogen atoms at the  $\alpha$ -carbon.<sup>27</sup> The protons bound to the  $\alpha$ -carbon appear at  $\tau \sim 7$ . Both these signals are well separated from the remaining absorptions which appear in the usual aliphatic region. All attempts to separate the various isomeric products in mixtures by gas-liquid partition chromatography were unsuccessful because of their extremely low volatility. Satisfactory product identification rests on correct elemental analyses of the high-vacuum distillation product mixtures and nmr and infrared spectra. The absence of any significant amount of impurity in the crude mixtures is indicated by the iden-

(26) H. Shechter and D. K. Brain, *J. Am. Chem. Soc.*, **85**, 1806 (1963).

(27) For example, the N-H proton of *neat* cyclohexylcyanamide appears as a doublet ( $J \sim 5$  cps) at  $\tau$  4.3 and that of *neat* *t*-butylcyanamide as a sharp singlet at  $\tau$  4.2.

of their spectral characteristics (nmr, infrared) compared with those of the analytically pure mixtures. In the intermolecular competition runs,  $N_3CN$  was polymerized in the appropriate hydrocarbon pair, the position of which was determined previously by

The mixtures of cyanamides produced were converted to the corresponding amino and methylamino derivatives by treatment with excess lithium aluminum hydride in boiling tetrahydrofuran; the relative amounts of amines were then determined by glpc. The pure amines were characterized by direct comparison of their retention times and mass spectrometric cracking patterns with those of authentic samples. Similarly, the reaction of NCN with the 1,2-dimethylcyclohexanes, the mixture of amines after reduction was analyzed by glpc, and the key isomers were characterized by direct comparison of glpc retention times and mass spectrometric cracking patterns with those of authentic samples.<sup>28</sup> Similar methods of conversion to amines for analysis were employed in the reaction of 1,1-dimethylcyclohexane with NCN and *cis*-1,2-dimethylhexane with nitric acid.

## Conclusions

Thermolysis of cyanogen azide at 40–50° affords free cyanonitrene which, in the absence of an inert diluent, inserts with tertiary C–H bonds stereospecifically. Information about the insertion process into the less reactive secondary and primary C–H bonds is not as easily obtainable experimentally. Here the mechanism may be deduced on the relative rates for direct insertion (path a) and intersystem crossing of singlet NCN to its triplet ground state ( $^1NCN \rightarrow ^3NCN$ ); i.e., if direct insertion is more rapid than intersystem crossing, singlet NCN will insert in a one-step process, whereas if the reverse is true, the reaction will occur by a hydrogen abstraction–recombination process by triplet NCN. Evidence will be presented in a subsequent paper that at least in the case of tertiary C–H bonds the direct insertion mechanism prevails. A hydrogen abstraction–recombination process by singlet NCN does not in all probability occur with either type of C–H

## Experimental Section<sup>29</sup>

Extreme caution should be exercised in handling cyanogen azide. It detonates with great violence and it should be prepared only in solvents. Solutions of cyanogen azide in paraffinic hydrocarbons can be handled safely, but should nevertheless be treated as potentially explosive because of its poor solubility in non-solvents. The concentration of such solutions should not exceed 10%.

K. E. Hamlin and M. Freifelder, *J. Am. Chem. Soc.*, **75**, 369 (1953).

All melting points and boiling points are uncorrected. Nmr spectra were measured with a Varian A-60 spectrometer and infrared spectra with a Perkin-Elmer 21 spectrometer. The glpc results were obtained under the following conditions: A, 2 m  $\times$  0.24 in. stainless steel column packed with 20% tetrakis(hydroxyethyl)ethylenediamine (TCEG) on 60–80 mesh Chromosorb W (not acid washed) at 101° with nitrogen at 155°, helium was used as the carrier gas at a flow rate of 1 ml/min; B, same as in A except column and vaporizer temperatures 102 and 165°, respectively; C, 2 m  $\times$  0.25 in. stainless steel column packed with 20% TCEG on 60–80 mesh Chromosorb W as in A and B at 119° and the vaporizer at 175°, carrier gas and flow rate were as in A and B; D, 2 m  $\times$  0.25 in. copper column packed with 10% 1,2,3-tris(2-cyanoethoxy)propane (TCEG) on 60–80 mesh Chromosorb R at 52° with the vaporizer at 120°; E, 12 ft  $\times$  0.75 in. stainless steel column of 20% THEED on Chromosorb W (not acid washed) at 110°, and a helium flow rate of 810 cc/min.

**Materials.** Activated sodium azide<sup>30</sup> was used throughout. Of the hydrocarbons, 2,3-dimethylbutane, 2,2-dimethylbutane, and *cis*- and *trans*-1,2-dimethylcyclohexane were "Phillips Research Grade" and were used without further purification. Cyclohexane, cycloheptane, cyclooctane, 3-methylpentane, 1,1-dimethylcyclohexane, and *n*-hexane were treated with concentrated sulfuric acid and carefully fractionated before use. The materials thus obtained were >99.6% pure by glpc (conditions D). Labeled potassium azide (ca. 95 atoms %  $^{15}N$  at positions 1 and 3) was purchased from Merck Sharp and Dohme of Canada.

**Thermolysis of Cyanogen Azide in *n*-Hexane.** Cyanogen chloride (50 ml) was allowed to evaporate into a stirred suspension of sodium azide (6.0 g) in *n*-hexane (30 ml) maintained under nitrogen and contained in a three-necked flask fitted with thermometer, inlet tube, and condenser held at –5 to 0° by a circulation coolant. The addition was made over a 2.5-hr period, while the temperature of the mixture was maintained at –4 to 0°. The suspension was then stirred at room temperature overnight, *n*-hexane (70 ml) was added, and the excess cyanogen chloride was removed at room temperature<sup>31</sup> at 100–200-mm pressure. The suspension was subsequently filtered under nitrogen pressure into a graduated cylinder. To the clear filtrate was then added more *n*-hexane to a total volume of 295 ml. A 2-ml sample of this solution gave 7 ml of gas when treated with trimethyl phosphite in an azotometer at 0–2° (46% yield).

The solution was subsequently transferred into a 500-ml, three-necked, round-bottomed flask fitted with thermometer and condenser. A water test meter was connected through a Dry Ice trap to the top of the condenser. When the solution was heated at 48–52° with stirring for 18 hr, 900 ml (~90%) of gas was evolved. The yellow hexane solution was subsequently filtered free of any residue, and the volatile constituents of the filtrate were evaporated at 40° under water-aspirator pressure to yield a residual orange oil. This was distilled in a molecular still at ~0.05  $\mu$  and a maximum bath temperature of 90°. The colorless distillate amounted to 2.76 g (53% yield based on  $N_3CN$ ) and the residual resin to 0.5 g. The infrared spectrum of the distillate exhibits characteristic strong bands at 3180 (N–H) and 2200 ( $C\equiv N$ )  $cm^{-1}$ . The nmr spectrum is equally consistent with signals at  $\tau$  4.2 (doublet), 7.0 (multiplet), and 8.3–9.2 (multiplet).

**Anal.** Calcd for  $C_7H_{14}N_2$ : C, 66.62; H, 11.18; N, 22.20. Found: C, 66.48; H, 11.12; N, 22.87.

**Thermolysis of Cyanogen Azide in 2,3-Dimethylbutane, 3-Methylpentane, and 2,2-Dimethylbutane.** A procedure similar to that described for *n*-hexane was employed. The results are given in Table III.

**Intramolecular Competition Runs.** The following general procedure was employed. Cyanogen azide was prepared by stirring overnight under reflux (~15°)<sup>32</sup> a mixture of 2.0 g of sodium azide and ca. 40 ml of cyanogen chloride under nitrogen. The appropriate hydrocarbon was then added, and the excess cyanogen chloride removed at room temperature<sup>31</sup> (100–200 mm). The suspension was subsequently filtered under nitrogen pressure and the clear filtrate made up to ca. 200 ml by further addition of hydrocarbon. The solution was transferred into a one-necked, round-bottomed flask fitted with a condenser, and the flask was placed in a constant-temperature water bath maintained at  $46.1 \pm 0.1^\circ$ . The solution was held at this temperature for ca. 21 hr; the theoretical amount of nitrogen had then been evolved. The mixture was then filtered free from any traces of precipitate that might be present, and the filtrate was concentrated to a tan oil under water-aspirator pressure and below 40°. A 250-cps nmr spectrum of the residual oil was determined immediately, and the areas of interest were carefully cut and weighed. The results of duplicate runs are shown in Table IV. In each case the nmr and infrared spectra of these mixtures were the same as those of their analytically pure counterparts described above.

The figures in Table IV were corrected for statistical factors and translated into the relative rates shown in Table I (A) by the following relations: a, for products derived from 2,3-dimethylbutane, tertiary product/primary product =  $(A_1 - A_2/2)/(A_2/2)$ ; b, for products derived from *n*-hexane and 2,2-dimethylbutane, secondary product/primary product =  $[A_1 - (A_2 - A_1)]/(A_2 - A_1)$ .

(30) P. A. S. Smith, *Org. Reactions*, **3**, 382 (1946).

(31) It is essential that the temperature be kept above +10° to avoid separation of a highly explosive layer of neat cyanogen azide.

(32) It is essential to keep the temperature of the condenser at ca. –5 to 0° to contain the cyanogen chloride (bp 12°). In the course of one run, failure of the cooling system led to a violent explosion.

<sup>a</sup> Mole %, determined by glpc under conditions D. <sup>b</sup> Average of four glpc determinations under conditions A. <sup>c</sup> Average of three glpc determinations under conditions C. <sup>d</sup> Weight %, A = cyclohexylamine, B = N-methylcyclohexylamine, C = 2-aminohexane, D = 2-methylaminohexane, E = 3-aminohexane, F = 3-methylaminohexane, G = cycloheptylamine, H = N-methylcycloheptylamine, I = cyclooctylamine, and J = N-methylcyclooctylamine. <sup>e</sup> In these runs, known mixtures of the amines were used for quantitative glpc calibrations.

**Intermolecular Competition Runs.** The procedure was essentially the same as that described for the intramolecular competition runs. The appropriate hydrocarbon mixture was added, the cyanogen chloride removed, the suspension filtered, and the filtrate made up to 200-ml volume. The exact composition of the mixture was determined by glpc. The reaction mixture was then heated at 46.1 ± 0.1° in a constant-temperature water bath for 20 hr. The crude cyanamides were isolated in the usual way and were treated with lithium aluminum hydride according to the following procedure.

A solution of the crude cyanamide mixture (3.0 g) in tetrahydrofuran (50 ml) was added with stirring to a boiling suspension of lithium aluminum hydride (5.0 g) in tetrahydrofuran (150 ml) over a period of 1.5 hr. The mixture was stirred under reflux for an additional 15 hr. It was cooled in an ice bath and treated carefully with a saturated aqueous solution of sodium sulfate until the slurry turned white. The mixture was filtered and the filter cake washed with tetrahydrofuran. The filtrate was made strongly acid with 25 ml of concentrated hydrochloric acid and evaporated to dryness to afford a hygroscopic, crystalline, tan solid. This product was dissolved in 15 ml of distilled water, and the resulting solution transferred into a 50-ml separatory funnel. The funnel was placed in an ice bath, and the solution was made strongly basic by the addition of sodium hydroxide pellets. The mixture was shaken vigorously; the layers were allowed to separate, and the dark upper layer was collected and dried over sodium hydroxide pellets under nitrogen and analyzed by glpc. The results are shown in Table V. All amines except 2- and 3-methylaminohexane were identified by direct comparison of their glpc retention times and

Temp, °C (mm)	Amount, g	$n_D^{25}$	Composition <sup>a</sup>
100–106 (38)	0.4	1.4639	11a, 35.7%; 11b, 17.0%
108–113 (39–42)	0.78	1.4654	11a, 8.0%; 11b, 14.8%

<sup>a</sup> Amounts were determined by glpc under conditions C. Structural assignments were made on the basis of mass spectrometric cracking patterns. Compound 11a: molecular ion at  $m/e$  127, 100% ion at  $m/e$  70; compound 11b: molecular ion at  $m/e$  141, 100% ion at  $m/e$  84.

was filtered; the filter cake was washed with ether, and the combined extracts were dried over sodium hydroxide pellets. The ether was then removed and the residual liquid distilled (see Table VII).

**Thermolysis of Cyanogen Azide in 1,1-Dimethylcyclohexane.** Cyanogen azide, prepared from 2.0 g of sodium azide and 40 ml of cyanogen chloride, was thermolyzed at  $46.25 \pm 0.05^\circ$  in 110 ml of 1,1-dimethylcyclohexane. The cyanamide mixture (2.5 g) was isolated as described previously. This product was subsequently reduced with lithium aluminum hydride in tetrahydrofuran in the usual manner. The amine mixture amounted to 2.0 g. Glpc analysis of the mixture under conditions C indicated the absence of 11a and 11b.

**Preparation of 1-Amino-1,2-dimethylcyclohexane.** This compound was prepared as described in the literature.<sup>28</sup> Nitration (aluminum nitrate nonahydrate) of a 2:1 mixture of *cis*- and *trans*-1,2-dimethylcyclohexane and subsequent catalytic hydrogenation (Raney nickel) of the resulting nitro compounds gave a stereoisomeric mixture of *cis*- and *trans*-1,2-dimethylcyclohexane. The component with the higher retention time (30.9 min, conditions A) constituted 51% of the mixture and the one with the lower retention time (20.3 min, conditions A), 42.4% of the mixture. The components with the higher and lower retention times are assigned the *cis* and the *trans* configurations, respectively. The two isomers were separated by preparative glpc under conditions E. Stereoisomers 14a and 15a exhibit identical mass spectrometric cracking patterns (100% ion at  $m/e$  70; molecular ion at  $m/e$  127). Their infrared spectra are identical except for minor differences in the fingerprint region.

**1-Methylamino-*trans*-1,2-dimethylcyclohexane and 1-Methylamino-*cis*-1,2-dimethylcyclohexane.** Stereopure 14a and 15a were converted to the monomethyl derivatives by the procedure described for the conversion of 11a to 11b.

1. *cis* Isomer 15b. A 2.5-g sample of the *cis*-amino compound 15a gave 0.77 g of colorless amine, bp  $81\text{--}82^\circ$  (33 mm). Glpc analysis under conditions A showed 54.8% 15a ( $RT$  (retention time) = 30.9 min) and 32.7% 15b ( $RT$  = 23.6 min). The mass spectrum of 15b shows 100% ion at  $m/e$  84 and molecular ion at  $m/e$  141.

2. *trans* Isomer 14b. A 2.5-g sample of 14a gave 0.57 g of amine. Glpc analysis under conditions A indicated 66.9% 14a ( $RT$  = 20.3 min) and 29.0% 14b ( $RT$  = 13.0 min). The mass spectrum of 14b shows 100% ion at  $m/e$  84 and molecular ion at  $m/e$  141 and is qualitatively identical with the spectrum of its stereoisomer 15b.

**Thermolysis of Cyanogen Azide in *cis*-1,2-Dimethylcyclohexane.** Cyanogen azide, prepared from 2 g of sodium azide and 40 ml of cyanogen chloride, was heated at  $46.05 \pm 0.05^\circ$  in 200 ml of *cis*-1,2-dimethylcyclohexane. The resulting mixture of cyanamides was isolated and converted to the corresponding amines (2.2 g) in the usual way (lithium aluminum hydride in tetrahydrofuran). The mixture was analyzed by glpc (conditions A) and consisted of 0.5% 14b ( $RT$  = 12.8 min), <0.3% 14a, 28.9% 15b ( $RT$  = 23.7 min), and 15.4% 15a ( $RT$  = 30.4 min). Compounds 14b, 15b, and 15a were identified mass spectrometrically.

**Thermolysis of Cyanogen Azide in *trans*-1,2-Dimethylcyclohexane.** The mixture of amines (2.0 g) was obtained by a procedure analogous to that described for the *cis* hydrocarbon. Glpc analysis under conditions A gave 25.3% 14b ( $RT$  = 12.8 min), 14.7% 14a ( $RT$  = 19.7 min), and <0.3% 15a. Compounds 14b and 14a were identified by their mass spectrometric cracking patterns.

**Nitration of *cis*-1,2-Dimethylcyclohexane.** A mixture of *cis*-1,2-dimethylcyclohexane (50 g) and 50% nitric acid (350 g) was stirred at the boiling temperature (oil bath at  $140^\circ$ ) for 3 hr. The mixture was allowed to cool to room temperature; the layers were separated, and the aqueous layer was cooled in ice and extracted with two 50-ml portions of ether. The ether extracts were combined with the organic layer and washed first with four 50-ml portions of 20% aqueous sodium hydroxide, then with water, and fi-

nally dried over Drierite. Removal of the ether and the excess hydrocarbon at  $50^\circ$  (10 mm) and distillation of the residue gave a pale yellow liquid (3.23 g, 4.6%), bp  $82\text{--}87^\circ$  (3–5 mm);  $n_D^{25}$  1.4667. This product was treated with lithium aluminum hydride in the usual way and glpc analysis of the crude amine mixture under conditions A indicated the presence of 14.2% 14a ( $RT$  = 19.5 min) and 14.6% 15a ( $RT$  = 30.0 min). The two materials exhibit essentially identical mass spectrometric cracking patterns with a molecular ion at  $m/e$  127 and a 100% ion at  $m/e$  70.

**Thermolysis of  $^{15}\text{N}$ -Labeled Cyanogen Azide in Cyclohexane.** Cyanogen azide in cyclohexane (290 ml) was prepared from isotopically labeled potassium azide (2.1 g) according to the procedure already described. This solution was heated at  $49\text{--}50^\circ$  overnight, and the crude cyclohexylcyanamide (2.27 g, 57%) was isolated in the usual way and distilled at ca.  $0.003 \mu$  to afford 1.54 g of pure 1. The purified cyanamide was suspended in 10 ml of distilled water, 20 drops of concentrated sulfuric acid was added, and the mixture was stirred under reflux for 0.5 hr. The precipitated white solid was isolated by filtration, washed with water, and dried in a drying pistol, yielding 1.1 g (63%) of cyclohexylurea, mp  $186\text{--}186.7^\circ$ . A suspension of this material (1.1 g) in tetrahydrofuran (30 ml) was added with stirring to a boiling mixture of lithium aluminum hydride (2.0 g) in tetrahydrofuran (130 ml) under nitrogen. The addition was made over 1 hr, and the mixture was stirred under reflux for an additional 24 hr. The usual work-up afforded a yellow liquid which was dried over sodium hydroxide pellets and distilled ( $10\text{--}20$  mm). The colorless distillate (2 + 3) amounted to 0.25 g. The corresponding unenriched materials were prepared analogously.

**Analysis.** Starting potassium azide was burned to nitrogen and the isotopic enrichment of this species determined mass spectrometrically: atom % of  $^{15}\text{N}$  in nitrogen = 3.26, total  $^{15}\text{N}$  in potassium azide =  $3.26 \times 3 = 9.78\%$ , atom % of  $^{15}\text{N}$  in the terminal position of azide less the  $^{15}\text{N}$  natural abundance (net enrichment):  $[(9.78 - 0.36)/2] - 0.36 = 4.35$ .

The amount of  $^{15}\text{N}$  in 1 and 2 was determined mass spectrometrically employing the ratio of intensities of molecular ion + 1 to molecular ion. The results are shown in Table VIII.

Table VIII. Ratio of Intensities of Molecular Ion + 1 to Molecular Ion at 70 ev

	1 ( $^{14}\text{N}$ ), %	1 ( $^{15}\text{N}$ ), %	2 ( $^{14}\text{N}$ ), %	2 ( $^{15}\text{N}$ ), %

	8.85	13.20	8.00	10.72
			8.12	10.74
			8.17	10.64
			8.20	10.74
Av	8.86	13.26	8.14	10.69
Total $^{15}\text{N}$ enrichment in 1 = 4.40%				
Total $^{15}\text{N}$ enrichment in 2 = 2.55%				

Compound 2 was burned to nitrogen and the isotopic enrichment was determined mass spectrometrically (in duplicate); total enrichment in 2 = 2.35%, 2.55%.

**Reaction of Norbornene with  $^{15}\text{N}$ -Labeled Cyanogen Azide.** Enriched cyanogen azide was prepared from 2 g of isotopically labeled potassium azide and 35 ml of cyanogen chloride. To the cyanogen chloride suspension was added 55 ml of water-free acetonitrile; the excess cyanogen chloride was removed at  $100\text{--}200$  mm, and the residual suspension was pressure filtered under nitrogen. The clear acetonitrile solution amounted to 55 ml and liberated 7.5 cc of gas ( $\text{N}_2$ ) per 1 ml of sample when treated with trimethyl phosphite. The solution was subsequently maintained at  $49^\circ$  for 2.5 hr. At the conclusion a 1-ml sample of the solution liberated 6.5 cc of gas. The mixture was cooled in an ice bath, and a solution of freshly distilled norbornene (6 g) in acetonitrile (30 ml) was added over 1.5 hr, while the temperature was maintained at  $-2$  to  $4^\circ$ . After the addition was complete (theoretical amount of gas had been evolved), the reaction mixture was held at room temperature for an additional 16 hr. Removal of the volatile constituents under water-aspirator pressure and at  $55^\circ$  gave 2.4 g of an orange oil. This product was dissolved in benzene (10 ml) and passed through a chromatographic column containing 100 g of grade IV

"Woelm" neutral alumina. Evaporation of the eluents (400 ml) afforded a slightly tan oil, which exhibited a strong infrared band at 2200 ( $\text{C}\equiv\text{N}$ ) and 1730 ( $\text{C}=\text{O}$ )  $\text{cm}^{-1}$ . Distillation of this material through a micro-Vigreux column gave pure cyanoaziridine as a colorless liquid (1.53 g, 41%), bp 97° (0.35 mm), the infrared spectrum of which showed a strong band at 2200  $\text{cm}^{-1}$  and no absorption at 1730  $\text{cm}^{-1}$ .

Removal of the nitrile group from 6 was accomplished as follows. A solution of the cyanoaziridine (1.53 g) in ether (15 ml) was added to a stirred suspension of lithium aluminum hydride (0.24 g) in ether (25 ml) over 20 min. The temperature of the mixture was maintained below 25° throughout the addition by an ice bath. The suspension was then stirred at reflux for 3 hr. The suspension was subsequently cooled with an ice-salt bath and treated with a saturated aqueous solution of sodium sulfate. The white suspension was filtered; the colorless filtrate was dried over anhydrous sodium sulfate and the ether removed. Distillation of the residual

oil through a short path head at 0.2–0.5 mm with a bath temperature of 150° afforded a colorless semisolid (0.80 g, 67%) which solidified immediately when placed on a porous plate. The infrared spectrum of this material was identical in all respects with that of an authentic sample.<sup>23</sup>

**Analysis.** Starting potassium azide was burned to nitrogen and the isotopic enrichment of this species determined mass spectrometrically: atom % of  $^{15}\text{N}$  in nitrogen = 3.25, total  $^{15}\text{N}$  in potassium azide =  $3.25 \times 3 = 9.75\%$ , atom % of  $^{15}\text{N}$  in terminal position of azide less the  $^{15}\text{N}$  natural abundance (net enrichment):  $[(9.75 - 0.36)/2] - 0.36 = 4.33$ .

Compounds 5 and 6 were converted to nitrogen, and the isotopic enrichment was determined mass spectrometrically (in duplicate): total enrichment in 5 = 4.18%, 4.38%; total enrichment in 6 = 3.90%, 4.19%.

## The Electronic Multiplicity of Thermally Generated Cyanonitrene<sup>1</sup>

A. G. Anastassiou<sup>2</sup>

Contribution No. 1258 from the Central Research Department, Experimental Station, E. I. du Pont de Nemours and Company, Wilmington, Delaware 19898. Received February 4, 1967

**Abstract:** The stereochemistry of the insertion of cyanonitrene, generated thermally from cyanogen azide, into the tertiary C–H bonds of *cis*- and *trans*-1,2-dimethylcyclohexane was studied in a variety of solvents. The stereospecificity observed when the reaction was conducted in the absence of a solvent was completely preserved in acetonitrile and fully destroyed in methylene bromide. In methylene chloride and ethyl acetate, the reaction is stereoselective. Triplet cyanonitrene displays a slightly more pronounced discrimination in selecting between secondary and tertiary C–H bonds than does singlet cyanonitrene. Mechanisms are discussed.

Recent years have witnessed a number of elegant and fruitful investigations concerning the electronic states of neutral electron-deficient fragments (carbenes,<sup>3</sup> nitrenes, etc.). In most cases, information about ground electronic states is readily available through a variety of spectroscopic methods such as electron paramagnetic resonance (epr) and flash photolysis. In contrast, information concerning electronic configurations of such species during the course of chemical reactions is not easily accessible and can only be adduced by an interplay of intuitive reasoning and experiment, the former being very often controversial. In chemical reactions, three situations arise: (1) the reacting species is in the ground electronic state, (2) the reacting species is in the first excited electronic state (usually of different multiplicity than the ground state), and (3) the reacting species is a composite of both ground electronic state and first excited electronic state. The great majority of reactions involving neutral electron-deficient intermediates is complicated by situation 3. The most widely employed criterion for arriving at the electronic multiplicity of a reacting carbene was advanced 11 years ago by Skell and Wood-

worth<sup>4</sup> and concerns the stereochemistry of addition of such a fragment to olefinic bonds. It states that singlet carbenes should add in one step to yield cyclopropanes in a stereospecific fashion, whereas the triplet counterparts ought to react by means of a diradical intermediate which, being essentially a free rotator, leads to stereorandom ring closure. Skell's postulate has received ample experimental support over the years and constitutes a reliable working hypothesis. Care must be exercised in its use, however, since, as has been repeatedly pointed out, it cannot be justified theoretically.<sup>4,5</sup> Three recent reports lend particularly strong support to the postulate. These deal with the effect of dilution by a nonolefinic substrate on the stereochemistry of addition of fluorenylidene<sup>6</sup> and dicyanocarbene,<sup>7</sup> both of which have triplet ground states,<sup>8,9</sup> to the isomeric 2-butenes and of carbethoxynitrene<sup>10</sup> to *cis*- and *trans*-4-methyl-2-pentene. In each case, the stereoselectivity

of the addition decreases drastically with increasing amount of diluent, a condition which favors situation 1 indicated above. Furthermore, in the case of dicyanocarbene<sup>7</sup> at high dilution, the same relative amounts of stereoisomeric cyclopropanes are formed starting from either olefinic isomer, in full agreement with Skell's free rotator model of the intermediate diradical.

## Results and Discussion

In the present paper, we present a full account of our work dealing with the electronic multiplicity of reacting cyanonitrene (NCN) generated thermally from cyanogen azide ( $N_3CN$ ). We chose not to study the stereochemical course of the addition of NCN to olefins because of a major experimental difficulty. Cyanogen azide itself reacts readily with olefinic functions<sup>11</sup> at room temperature, with over-all loss of molecular nitrogen, to yield products which, in the absence of appropriate isotopic labeling, are indistinguishable from those expected to form from NCN. Hence, we employed the stereochemistry of the insertion reaction into the C-H bonds of paraffinic hydrocarbons as a criterion of electronic multiplicity.

**Electronic Structure of NCN.** In the preceding paper<sup>12</sup> we mentioned that NCN has been studied by a variety of spectroscopic methods and the configuration of the ground electronic state and a few excited states determined. The information derived from these studies is compiled in Figure 1. It is interesting to consider the various configurations in connection with their ability to undergo stereospecific reactions with C-H bonds and olefinic functions. In so doing, we will not discuss the triplet states since here the stereochemistry of the reaction is independent of symmetry and configuration and depends only on factors succeeding the homolytic bond-breaking step, such as the magnitude of the rate of radical recombination *vs.* that of loss of configurational integrity, both of which are sensitive functions of environment.

The *donor* molecular orbitals (highest occupied MO's) of C-H and C=C bonds are of symmetry<sup>13</sup>  $\sigma_g$  and  $\pi_u$ , respectively. In the transition state, these could interact in either a bonding or antibonding fashion depending on the symmetry of the *acceptor* MO (lowest unoccupied) of the electron-deficient species. In the present case, since the transition state almost certainly involves interaction of a single nitrogen atom

Figure 2. Symmetry requirements of cyanonitrene in addition and insertion reactions.

of NCN with the C-H or the C=C bond, the symmetry of the *acceptor* MO as a whole is of no consequence and what is important is the local symmetry of that MO on the interacting nitrogen atom. This, coupled with the cylindrical symmetry of linear NCN, suggests that the nature of the interaction ought to be independent of the  $\pi$  symmetry of NCN, *i.e.*, both the  $\pi_g$  and  $\pi_u$  MO's of NCN can interact with C-H and C=C bonds in a bonding fashion. This is shown diagrammatically (molecular axis of NCN ( $z$ ) perpendicular to the plane of the paper) in 4 and 5 of Figure 2. In Figure 2 are also shown the various  $\pi$ -orbital combinations of linear NCN. The two low-lying singlets of NCN,  $^1\Sigma_g^+$  and  $^1\Delta_g$ , are similar with respect to symmetry of the *acceptor* MO(s), which in both cases is  $\pi_g$ , but differ in the way this degenerate MO is occupied. In  $^1\Sigma_g^+$ , each  $\pi_g$  is occupied singly whereas in  $^1\Delta_g$ , one is filled and the other empty (Figure 1). This difference in the occupancy of the  $\pi_g$  MO will in all probability determine the nature of overlap in the transition state. Thus the  $^1\Sigma_g^+$  state having evenly occupied *acceptor* MO's will probably overlap with the *donor* MO's of C-H and C=C in the fashion shown in 4 and 5, whereas electron repulsion considerations would suggest that the  $^1\Delta_g$  state ought to interact as shown in 6 and 7, with maximum overlap occurring between the *donor* MO and the empty  $\pi_g$  MO of the acceptor. Translating this crude picture into stereochemistry, we conclude that of the two low-lying singlet states,  $^1\Sigma_g^+$  should react stereospecifically in a one-step, three-center process whereas the  $^1\Delta_g$  state could probably react by way of the dipolar intermediates shown in 8 and 9 for C-H insertion and C=C addition, respectively. This latter process could lead to nonstereospecific results.

The higher energy singlet  $^1\Pi_u$  poses an interesting problem in connection with insertion and addition reactions. Here, one  $\pi_g$  and one  $\sigma_u$  MO are singly occupied, and we have a situation where two paired electrons differ widely in energy. This energy difference will weaken the pairing between the two electrons, and it is not inconceivable, especially since the two electrons are in MO's of different spatial symmetry, that enough weakening could occur so as to allow the two electrons to behave independently. If this occurs, it would be possible for the  $^1\Pi_u$  state to react with C-H and C=C bonds by a radical process commonly reserved for triplet species. It should be noted, however, that reaction of NCN in its  $^1\Pi_u$  state is very unlikely irrespective of the substrate employed since its deactiva-

tion to either the  $^1\Sigma_g^+$  or  $^1\Delta_g$  state ought to occur very rapidly compared to chemical reaction.

**Controlled Generation and Reaction of Singlet and Triplet NCN.** In previous work,<sup>12</sup> we studied the stereochemical course of the insertion reaction of thermally generated NCN into the tertiary C-H bonds of the two stereoisomeric 1,2-dimethylcyclohexanes and found it to occur with virtually complete stereospecificity. This result is best rationalized by assuming that the reaction occurs in one step by way of singlet NCN. The singlet nature of the reacting NCN is also suggested from considerations of spin conservation in the thermal fragmentation of  $N_3CN$  as well as the experimental conditions employed. Thus the low decomposition temperature strongly suggests that singlet  $N_3CN$  fragments to singlet molecular nitrogen<sup>14</sup> and, by the principle of conservation of spin, to singlet NCN which in the absence of a solvent would probably undergo reaction prior to collisional deactivation to the lower energy  $^3\Sigma_g^-$  state. Nevertheless, the stereochemical results can also be accommodated by a hydrogen abstraction by triplet NCN followed by spin inversion and recombination of the resulting radical pair, provided these latter processes are rapid compared to configurational inversion of the hydrocarbon radical.<sup>15</sup> To obtain definitive information concerning the nature of reacting NCN, it was therefore necessary to design experiments which would unambiguously distinguish between the two mechanisms. One simple way of achieving this is by inducing NCN to insert nonstereospecifically under conditions strongly favoring the presence of triplet NCN. We have examined this possibility by conducting the insertion reaction in the presence of various inert diluents. Under these conditions, collisional deactivation of the originally formed NCN to its  $^3\Sigma_g^-$  ground state should compete favorably with reaction. In the course of these experiments, we have also uncovered a thermochemical heavy atom effect. Since this effect provided most of the rationale in designing our experiments, it appears appropriate at this point to briefly summarize its mechanism.

The ability of heavy atoms to promote spin-forbidden electronic transitions is a well-recognized phenomenon and has been the subject of extensive spectroscopic and theoretical studies.<sup>16</sup> Both intramolecular (heavy atom incorporated in the substrate) and intermolecular (heavy atom incorporated in the solvent) "heavy-atom" effects have been observed spectroscopically. For example, the ultraviolet spectrum of 9,10-dibromoanthracene in a light solvent exhibits a fairly intense singlet to triplet ( $S_0 \rightarrow T_1$ ) absorption, whereas that of the parent hydrocarbon, determined under the same conditions, does not. Also the spectrum of neat 1-chloronaphthalene does not possess an  $S_0 \rightarrow T_1$  band, whereas the

spectrum of the same molecule determined in ethyl iodide does possess one. There exists a formal similarity between the deactivating processes available to the photoexcited states of a stable molecule and those open to carbenes and nitrenes. In both cases, conservation of spin requires the originally produced state to be a singlet which given an appropriate environment and enough time could decay to a lower energy triplet. However, the similarity ends here since the  $S_1 \rightarrow T_1$  intersystem crossing in the photoexcited substrate has to compete with the far more efficient spin-allowed  $S_1 \rightarrow S_0$  process, whereas in the case of an electron-deficient fragment with a triplet ground state intersystem crossing  $S_1 \rightarrow T_0$  is the only path available for deactivation. This lack of spin-allowed deactivation in most nitrenes and carbenes makes the use of external perturbations to the quantization of spin, such as the "heavy-atom" effect, exceedingly valuable in determining and controlling electronic multiplicity chemically. Two distinct processes are necessary for efficient collisional intersystem crossing which in the present case involves an  $S_1 \rightarrow T_0$  transition: (1) vibrational deactivation of the vibronically excited molecule to low vibrational levels of the first excited electronic state, from which energy transfer to high vibrational levels of the ground state can occur; and (2) removal of spin forbiddenness through coupling of spin and orbital angular momenta. The first process is strictly collisional and should depend on the number of degrees of freedom available to the perturbing molecule, as well as the number of perturbing molecules,<sup>17</sup> whereas the second is a function of the amount of spin-orbit coupling introduced by the perturber molecule which in turn depends on the spin-orbit coupling constant ( $\zeta$ ) of the atom responsible for the perturbation. Some relevant  $\zeta$  values are:<sup>18</sup> C, 28; N, 70; O, 152; Cl, 587; Br, 2460; and I, 5060  $\text{cm}^{-1}$ . For the case of NCN, the over-all mechanism for collisional deactivation is depicted in Scheme I.

#### Scheme I

It is clear, therefore, from these considerations that an inert solvent containing one or more heavy atoms or other perturbing functionalities should fulfill the various requirements for efficient relaxation to the ground electronic state. With this in mind and because in the absence of a solvent insertion of NCN into the C-H bonds of *cis*- and *trans*-1,2-dimethylcyclohexane occurs stereospecifically, we studied this reaction employing  $\text{CH}_2\text{Cl}_2$ ,  $\text{CH}_2\text{Br}_2$ ,  $\text{CH}_3\text{CN}$ , and  $\text{CH}_3\text{COOC}_2\text{H}_5$  as solvents. The results are compiled in Table I.

It is amply clear from the data in Table I that the insertion reaction can be induced to occur nonstereospecifically by the use of appropriate solvents. The results obtained with the methylene halide solvents (reactions 4-12) are especially interesting. Both  $\text{CH}_2\text{Cl}_2$  and  $\text{CH}_2\text{Br}_2$  contain the same number and type of atoms and hence should be equally effective in deacti-

(14) The alternate process, *i.e.*,  $N_3CN \xrightarrow{\Delta} ^3N_2 + ^3\text{NCN}$ , is undoubtedly unfavorable energetically since the  $^1N_2 \rightarrow ^3N_2$  energy separation is in all probability much larger than the  $^1\text{NCN} \rightarrow ^3\text{NCN}$  energy gap.

(15) Inversion of the asymmetric center with respect to NHCN can occur either by rotation of the hydrocarbon radical by  $180^\circ$  prior to recombination with the counterradical or by migration of NHCN to a site at which recombination would invert the configuration of the original hydrocarbon.

(16) Heavy atoms are known to enhance the probability of spin-forbidden transitions through coupling of spin and orbital angular momenta. See, for example, C. D. Dijkstra and G. J. Hoijtink, "Quantum Chemistry Symposium," *Tetrahedron Suppl.*, 2, 179 (1963); and J. N. Murrell, "The Theory of the Electronic Spectra of Organic Molecules," John Wiley and Sons, Inc., New York, N. Y., 1963, pp 294-300.

(17) For a striking example of the effect of the number of degrees of freedom available to an inert diluent on the rate of intersystem crossing of methylene, see R. F. Bader and J. I. Generosa, *Can. J. Chem.*, 43, 1631 (1965).

<sup>a</sup> Volume per cent of hydrocarbon in solvent. <sup>b</sup> Maintained to within  $\pm 0.1$ . <sup>c</sup> Yield of a 1:1 mixture of amino- and methylamino-1,2-methylcyclohexanes, based on sodium azide. <sup>d</sup> Compounds 10 and 11 are

ating NCN by a strictly collisional process. In actual fact, however, the heavier of the two solvents appears to be more efficient in the over-all deactivation of NCN. This is most readily seen from the results of reactions 5, 9, and 10. In CH<sub>2</sub>Cl<sub>2</sub> the reaction loses its stereospecificity in part but still exhibits considerable stereochemical bias toward retention of the original configuration,<sup>19</sup> whereas in CH<sub>2</sub>Br<sub>2</sub> the reaction is stereochemically random, yielding the same mixture of stereoisomers irrespective of the stereochemical identity of the pure hydrocarbon substrate (reactions 9 and 10) or the hydrocarbon mixture (reaction 11). The greater efficacy of CH<sub>2</sub>Br<sub>2</sub> in destroying the stereospecificity of the reaction is indicated even more strikingly from the results of reactions 7 and 8. Here it is seen that in H<sub>2</sub>Cl<sub>2</sub> the insertion is still strongly stereoselective even when the ratio of solvent to hydrocarbon is increased by a factor of 5 over that of reactions 4, 5, 9, and 10. We interpret these results to mean that NCN reacts partly as a triplet in CH<sub>2</sub>Cl<sub>2</sub> and exclusively as a triplet in H<sub>2</sub>Br<sub>2</sub>, and we conclude that the hydrogen-abstraction-combination process by which in all certainty this species reacts with C-H bonds occurs in a completely nonstereospecific fashion. This is in full agreement with the notion that triplet NCN is produced from decay of singlet NCN since CH<sub>2</sub>Br<sub>2</sub>, possessing a heavier halogen, is required by theory to be the more effective of the two solvents in bringing about singlet-triplet interconversions. The widely different effectiveness of the two halocarbon solvents in destroying the stereospecificity of the reaction clearly eliminates the possibility that we are witnessing deactivation of an origi-

nally produced stereospecifically inserting singlet, say  $^1\Sigma_g^+$ , to a lower energy, nonstereospecifically inserting singlet, say  $^1\Delta_g$ . Deactivation within such a spin-allowed process should be strictly collisional and should be independent of the nature of the halogen in the inert diluent. In this context, it should be noted that the results of reactions 4-12 can be rationalized without invoking a difference in the effectiveness between CH<sub>2</sub>Cl<sub>2</sub> and CH<sub>2</sub>Br<sub>2</sub> in deactivating NCN. For example, it could be argued that the same relative amounts of singlet and triplet NCN are produced in both solvents but that in CH<sub>2</sub>Cl<sub>2</sub>, unlike CH<sub>2</sub>Br<sub>2</sub>, the hydrocarbon fragment has a good memory of its origin, and recombination leads to product in a stereoselective fashion. In view of the similarity of the two halocarbons, we consider such a process to be a very poor alternative to the operation of a "heavy-atom" effect. Alternatively it could be rationalized that the different results in the two halocarbons are due to partial reaction of NCN with solvent. At first glance, this explanation is especially appealing because of the lower yields observed in the halocarbons. However, to explain the results on this basis, one has to assume that CH<sub>2</sub>Br<sub>2</sub> scavenges singlet NCN exclusively whereas CH<sub>2</sub>Cl<sub>2</sub> reacts with both spin variants of NCN. Again the structural similarity of the two solvents makes this situation very unlikely. In connection with the poorer yields observed when the reaction was carried out in the halocarbons, it should be noted that these do not detract in any way from the significance of the stereochemical results. For example, even on the extreme assumption that the difference in yields between the reactions carried out in CH<sub>2</sub>Cl<sub>2</sub> and CH<sub>2</sub>Br<sub>2</sub> (20-34%) and those conducted in the absence of a solvent (44-46%) is due exclusively to

(19) The configurational assignment rests on rational assumptions rather than experimental fact (see ref 12).

reaction of singlet NCN with solvent, one can readily estimate a minimum stereochemical crossover of 17% in  $\text{CH}_2\text{Cl}_2$  and 22% in  $\text{CH}_2\text{Br}_2$ , as compared to <2% in the neat hydrocarbon.

Acetonitrile presents an interesting case. It is seen from the results of reactions 13 and 14 that this solvent is completely effective in preserving the stereospecificity of the reaction. Two possible explanations come to mind: (1) acetonitrile is totally ineffective in promoting singlet to triplet interconversions, and (2) triplet NCN is produced but is trapped effectively by  $\text{CH}_3\text{CN}$ . The low over-all yields of reactions 13 and 14 point strongly to the latter explanation as the correct one. In fact, it is reasonable to assume that an electron-deficient molecule such as  $\text{CH}_3\text{CN}$  would react preferentially with the less electrophilic triplet NCN. For example, for reaction of NCN with the C-H bonds of acetonitrile, there should be, for obvious reasons, a distinct preference for hydrogen abstraction by triplet NCN over direct insertion by singlet NCN. These two processes are depicted by 12 and 13, respectively. In great con-

trast to acetonitrile, ethyl acetate is almost as ineffective as  $\text{CH}_2\text{Br}_2$  in preserving stereospecificity, as is seen from the results of reactions 15 to 18. We can conceive of a number of reasons as to why this should be so. (1) Ethyl acetate, containing a greater number of atoms than the other inert diluents studied here, ought to be the most effective in the purely collisional part of the deactivation process. In addition, the carbonyl functionality in all probability introduces some triplet character to the ground state<sup>20</sup> of ethyl acetate, a property that should make this solvent effective in promoting intersystem crossing in NCN by the mechanism in Scheme I. (2) Triplet NCN could form from singlet NCN by a process involving spin exchange with the solvent, *i.e.*,  $^1\text{NCN} + {}^1[\text{CH}_3\text{COOC}_2\text{H}_5] \rightarrow {}^3\text{NCN} + {}^1[\text{CH}_3\text{COOC}_2\text{H}_5]$ . (3) The loss of stereospecificity may be due to reaction of singlet NCN by a hydride-abstraction-recombination process ( $\text{RH} + {}^1\text{NCN} \rightarrow \text{R} + \text{N} \cdot \text{HCN} \rightarrow \text{RNHCN}$ ) which ought to be more favorable in ethyl acetate than in the less polar halocarbon solvents. (4) The presence of relatively large amounts of triplet NCN could be a consequence of preferential scavenging of singlet NCN by solvent. Of these four, possibilities 2 and 3 can be eliminated fairly readily. In (2), the occurrence of a spin-transfer process between NCN and solvent requires that the  $S_0 \rightarrow T_1$  energy separation in ethyl acetate be smaller than or equal to the  $T_0 \rightarrow S_1$  energy gap in NCN. This is not the case;  $T_1$  in ethyl acetate is probably in the vicinity of 130 kcal/mole above the ground state<sup>21</sup> whereas, as one can readily see from Figure 1, the maximum possible  $T_0 \rightarrow S_1$  separation in the NCN system has to be less than 3.72 eV or 87 kcal/mole.<sup>22</sup> Pos-

(20) This is a consequence of the small singlet to triplet energy gap which characterizes  $n \rightarrow \pi^*$  states.

(21) This value represents the energy of the first excited  $n \rightarrow \pi^*$  singlet in ethyl acetate (J. G. Calvert and J. N. Pitts, Jr., "Photochemistry," John Wiley and Sons, Inc., New York, N. Y., 1966, p. 429). Experience suggests that the energy of the first excited triplet should be close to this value.

sibility 3 can be reasonably dismissed on the argument that if hydride abstraction occurs in ethyl acetate, it should occur in acetonitrile as well, since both solvents ought to provide equally favorable polar environments. The complete stereospecificity of the reaction in acetonitrile attests to the absence of such a two-step process. The two remaining possibilities (1 and 4) are both attractive, but a distinction between them is not possible on the available information. It is quite possible that ethyl acetate derives its efficacy for destroying the stereospecificity of the reaction from both processes.

The results collected in Table I are best rationalized by the set of reactions shown in Scheme II. Within

Scheme II

this mechanism,  $k_1$  is much larger than  $k_2$  in the absence of a solvent, comparable to  $k_2$  in  $\text{CH}_2\text{Cl}_2$  and much smaller than  $k_2$  in  $\text{CH}_2\text{Br}_2$  and possibly  $\text{CH}_3\text{COOC}_2\text{H}_5$ . In  $\text{CH}_3\text{CN}$ ,  $k_6$  is probably large compared to  $k_3$ , leading to results identical with those obtained in the case where  $k_1 \gg k_2$ . In  $\text{CH}_3\text{COOC}_2\text{H}_5$ , a large  $k_6$  may be partly responsible for the similarity of the results to those obtained when  $k_2 \gg k_1$ . It should be noted that any radical processes involving attack by substrate or solvent radicals on  $\text{N}_2\text{CN}$  can be reasonably dismissed since under these conditions stereoisomerization of the hydrocarbon by way of its radical should set in. In all cases, the recovered hydrocarbon was uncontaminated with its isomer. The stereochemical details of the reaction (employing the *cis* hydrocarbon as reference) are depicted in Scheme III. Here equilibration between the stereoisomeric radicals should be a rapid process compared with over-all recombination.

Scheme III

The ready and efficient environmental control of the electronic multiplicity of NCN described here provides a convenient means for studying reactions of the two spin variants separately. In order to determine the elec-

(22) The assumption here is that the usual energy alternation of singlets and triplets holds for the low-energy states of NCN, *i.e.*,  $E(^1\Delta_u) < E(^3\Pi_u) < E(^1\Pi_u)$ .

multiplicity of NCN in a certain reaction, one to know the rate of that reaction relative to the of insertion into the tertiary C-H bonds of 1,2-dimethylcyclohexane. Reactions that involve a lower  $\gamma$  path than insertion into the tertiary C-H bonds occur by way of singlet NCN when conducted in the absence of a solvent. Conversely under the conditions, NCN could enter reactions that are faster than the reference reactions as either a singlet or triplet. Furthermore, these latter reactions should occur exclusively through triplet NCN when conducted in  $\text{I}_2\text{Br}_2$ . The complexity of the 1,2-dimethylcyclohexanes poses a serious problem in their use as reference compounds since they produce a large number of isomeric cyanamides, some of which may interfere in the isolation and structural elucidation of the product(s) of interest. Hence, we examined the structurally simpler cyclic substrates, cyclohexane and cyclopentane, as ideal reference materials. The results are shown in Table II. It is clear from the data that the difference in reactivity between the tertiary C-H bonds of the dimethylcyclohexanes and the methylene functions of the cycloalkanes toward singlet NCN is quite small, indicating that the two cycloalkanes could conceivably be used as reference materials. These results also indicate a small difference between the reactivities of the  $\gamma$  C-H bonds of *cis*- and *trans*-1,2-dimethylcyclohexane. One can estimate a factor of 1.7 in favor of the *trans* isomer. Interestingly, the same factor can be determined from the results of reaction 3 and those of 4 and 5 in conjunction with those of 9 and 10 shown in Table I. This small but reproducible difference in reactivity may be due to steric reasons since the tertiary hydrogens of the *trans* compound, being *cis* to the methyl groups, should be less accessible sterically. However, the difference is fairly small and could be the result of a small experimental error as well. Another interesting feature of the results of Table II is that triplet NCN discriminates slightly better (2.1 times) than singlet NCN between tertiary and secondary C-H bonds. This is consistent with the lower energy content of singlet NCN.

I. Relative Affinity of NCN for the Tertiary C-H Bonds and *trans*-1,2-Dimethylcyclohexane and the C-H Bonds of Cyclopentane and Cyclohexane at  $43.5 \pm 0.1^\circ$

Reaction	Solvent	Hydrocarbon <sup>a</sup>	C-H bond	Affinity <sup>b,c</sup>
19	None	A	3	4.2
		C	2	1.0
		B	3	2.4
20	None	B	3	2.4
		C	2	1.0
		D	3	3.5
21	None	B	3	3.5
		D	2	1.0
		C	3	5.0
22	$\text{CH}_2\text{Br}_2$	B	3	5.0
		C	2	1.0

<sup>a</sup> A, *cis*-1,2-dimethylcyclohexane; B, *trans*-1,2-dimethylcyclohexane; C, cyclopentane; and D, cyclohexane. <sup>b</sup> In each reaction, the secondary C-H bonds are assigned the arbitrary value of 1.0. <sup>c</sup> Values are corrected for statistical factors.

**Product Analysis.** The information collected in Tables I and II was obtained as follows. Dilute solutions of  $\text{N}_3\text{CN}$  in the appropriate hydrocarbon(s) and the mixtures were thermolyzed at the temperatures indicated. The temperatures were necessary to effect thermolysis

at reasonable rates in the more polar solvents  $\text{CH}_3\text{CN}$  and  $\text{CH}_3\text{COOC}_2\text{H}_5$  in view of the greater stability of  $\text{N}_3\text{CN}$  in such media. A control experiment in  $\text{CH}_2\text{Br}_2$  at the higher temperature (reaction 12) indicated that the results are not temperature dependent within the narrow temperature range employed here. The crude mixtures of cyanamides were converted to the corresponding amino and methylamino compounds by treatment with a large excess of lithium aluminum hydride in boiling tetrahydrofuran. The mixtures of amines were analyzed by gas-liquid partition chromatography (glpc), and the amines of interest, 14 to 17, identified by direct comparison of their retention times and mass spectrometric cracking patterns with those of authentic materials.<sup>23</sup> The yields indicated are those of crude 1:1 mixtures of amino and methylamino compounds and are based on the amount of sodium azide employed in the preparation of cyanogen azide. The yields of all reactions conducted in the absence of a solvent were calculated from the weight of the crude amine mixture. The yields of the reactions which were carried out in a solvent were those calculated from the weight of the crude amines multiplied by a factor which was obtained by dividing the total glpc area of the amine mixture from that reaction by the total glpc area of the amine mixture obtained from the same hydrocarbon in the absence of a solvent. This method of calculation rests on the assumption that all volatile components in the product mixture of the reaction conducted in a solvent are amines derived from the hydrocarbon substrate(s). That this is a valid assumption is indicated from the virtual identity of the glpc patterns of mixtures from reactions in different solvents containing comparable amounts of the various stereoisomers. For example, the glpc patterns from reactions 13, 14, 15, and 16 are the same as those from 1, 2, 9, and 10, respectively. Only in one case (reaction 21) did the retention times of two amines of interest coincide. The amines were N-methylcyclohexylamine (16b) and 1-amino-*trans*-1,2-dimethylcyclohexane (15a). The relative amounts of these two components were estimated from the relatively constant ratio in which 15a and 15b are present in the various amine mixtures.

## Conclusion

The results reported in this paper indicate that the thermolysis of cyanogen azide in the temperature range of  $41$ – $53^\circ$  proceeds with conservation of spin to yield singlet NCN which inserts stereospecifically into tertiary C-H bonds. This species can be readily deactivated through collisions with a suitable inert diluent to triplet NCN which reacts with tertiary C-H bonds by a totally stereorandom hydrogen-abstraction-recombination process. Triplet NCN is slightly more selec-

(23) Authentic amines 14a, 14b, 15a, and 15b were prepared according to K. E. Hamlin and M. Freifelder, *J. Am. Chem. Soc.*, **75**, 369 (1953). See also ref 12.

Table III. Identifying Features of the Amines

were better than 99.7% pure by glpc and were used without further purification. Of the solvents, ethyl acetate was "Fisher Reagent Grade," and acetonitrile (anhydrous) and dichloromethane were Eastman (White Label) and were used without further purification. Methylene bromide was purified by careful distillation immediately before use (better than 99.5% pure).

**General Procedure of the Reaction.** In the absence of a solvent, the reaction was carried out in the manner described in the preceding paper.<sup>12</sup> When a solvent was employed, the general procedure was as follows. Cyanogen azide was prepared in the usual manner<sup>13</sup> from sodium azide (2 g) and cyanogen chloride (ca. 50 ml). The appropriate solvent (ca. 100 ml) was added and the excess cyanogen chloride removed at 200–300 mm, through the condenser maintained at 5–10°, until the temperature of the sus-

tive in its reaction between tertiary and secondary C–H bonds than is singlet NCN, as is expected from its lower energy content. Overlap considerations suggest that, in the absence of perturbation in the transition state, the  $^1\Sigma_g^+$  state is more likely to react stereospecifically with C–H and C=C bonds than is the  $^1\Delta_g$  state.

### Experimental Section<sup>24</sup>

**Materials.** Of the hydrocarbons employed, the 1,2-dimethylcyclohexane and cyclopentane were "Phillips Research Grade," and the cyclohexane was "Eastman Spectrograde." They all

(24) Infrared spectra were obtained with a Perkin-Elmer 21 spectrometer, and mass spectra were determined with a Bendix time-of-flight mass spectrometer. The glpc results were obtained under the following conditions: A, 2 × 2 m × 0.25 in., stainless steel column packed with

pension was 20–25°. The amount of time required for this operation varies with the solvent; polar media such as acetonitrile and ethyl acetate require longer periods. The suspension was filtered under nitrogen pressure and the filtrate made up to a total of 300 ml with solvent. To this was added the appropriate hydrocarbon or hydrocarbon mixture<sup>25</sup> (30 ml) and the well-mixed solution transferred into a one-necked, 500-ml flask fitted with a condenser and connected (through the top of the condenser) to a wet test meter by way of a trap maintained at Dry Ice-acetone temperature.

20% tetrakis(hydroxyethyl)ethylenediamine (THEED) on 60–80 mesh Chromosorb W (not acid washed) at 101° with the vaporizer at 165°; helium was used as the carrier gas at a flow rate of 74 cc/min; B, 2 m × 0.25 in., copper column packed with 20% 1,2,3-tris(2-cyanoethoxy)propane (TCEGE) on 60–80 mesh Gas Chromosorb R at 52° with the vaporizer at 120°; helium was used as the carrier gas at a flow rate of 67 cc/min.

(25) The composition of this mixture was determined by glpc under conditions B.

The flask was immersed in a constant-temperature water bath and maintained to within  $0.1^\circ$  of the required temperature overnight, after which period the theoretical amount of nitrogen had evolved. The mixture was then filtered free of any traces of precipitate that might be present and a glpc sample (ca. 1 ml) taken from the filtrate and analyzed for type of hydrocarbon present, under conditions B. The remainder of the filtrate was then concentrated first under water-aspirator pressure at ca.  $30\text{--}40^\circ$  and then at 3–5 mm and room temperature to yield a light orange viscous oil (ca. 2 g), which exhibited strong characteristic  $\text{--NHCN}$  infrared absorption at  $3200\text{ (N--H)}$  and  $2200\text{ cm}^{-1}\text{ (C}\equiv\text{N)}$ . The cyanamide mixture was then converted to an amine mixture by treatment with a great excess of lithium aluminum hydride in boiling tetrahydrofuran as described in the preceding paper.<sup>12</sup> The mixture of amines was analyzed by gas-liquid partition chromatography

under conditions A, and the amines of interest were identified by direct comparison of their glpc retention times and mass spectro-metric cracking patterns with those of authentic samples. The relevant data employed in the identification are shown in Table III. The quantitative results are compiled in Tables IV and V. The yields tabulated were calculated from the weights of the crude amine mixtures in conjunction with the total glpc area observed in each case. For example, the yield of reaction 7 based on weight of amine mixture (assuming a 1:1 mixture of amino and methyl-amino compounds) is 39% which, after correction for total amount of volatile material, becomes  $39 \times 87/100 = 34\%$ . The various reaction numbers correspond to those shown in Tables I and II.

**Acknowledgment.** The author is indebted to Miss Patricia Canfield for the glpc determinations.

## The Preparation and Properties of 13,14-Diazatricyclo[6.4.1.1<sup>2,7</sup>]tetradeca-3,5,9,11-tetraene and Its Derivatives

Alexander L. Johnson and Howard E. Simmons

Contribution No. 1287 from the Central Research Department, Experimental Station, E. I. du Pont de Nemours and Company, Wilmington, Delaware 19898.  
Received February 10, 1967

**Abstract:** The thermodynamically more stable dimers of 1-cyano-, 1-ethoxycarbonyl, 1-*t*-butoxycarbonyl, and 1-methylazepine are all representatives of the new 13,14-diazatricyclo[6.4.1.1<sup>2,7</sup>]tetradeca-3,5,9,11-tetraene ring system. These compounds are formed from kinetically produced isomers which rearrange on further thermal treatment to the doubly bridged piperazine system. The chemistry of this system and the fully reduced 13,14-diazatricyclo[6.4.1.1<sup>2,7</sup>]tetradecane system is discussed in detail.

Recently, brief descriptions have appeared<sup>1</sup> of the dimers of 1-cyanoazepine (1a),<sup>1a,b</sup> 1-ethoxycarbonylazepine (1b),<sup>1c</sup> and 1-methylazepine (1c).<sup>1d</sup> Our more recent observation of the dimerization of 1-*t*-butoxycarbonylazepine (1d) suggests that this is a general property of the azepine nucleus. This paper is

concerned with the thermally more stable dimers which belong to the new 13,14-diazatricyclo[6.4.1.1<sup>2,7</sup>]tetradeca-3,5,9,11-tetraene ring system (3).

At relatively low temperatures, the parent azepines dimerize readily to kinetically controlled products which lack an element of symmetry. In particular, 1a dimerizes at  $25\text{--}60^\circ$  to a white crystalline product, mp  $220\text{--}221^\circ$  dec,<sup>1a,b</sup> 1b dimerizes at  $130^\circ$  to a white solid, mp  $78^\circ$ ,<sup>1c</sup> and 1c forms a colorless solid, mp  $66^\circ$ .<sup>1d</sup> The structure of the dimer of 1a is different from that postulated for the dimers of 1b (2)<sup>1c</sup> and 1c<sup>2</sup> and it will

be discussed elsewhere.<sup>2</sup> At higher temperatures, thermally more stable isomers are obtained which are 13,14-disubstituted 13,14-diazatricyclo[6.4.1.1<sup>2,7</sup>]tetradeca-3,5,9,11-tetraenes (3). Specifically, the dimer

of **1a** is converted smoothly to **3a** at 210°,<sup>1b</sup> either **1b** or **2** is converted to **3b** at 200°,<sup>1c</sup> **1c** to **3c** above 0°,<sup>1d</sup> and **1d** to **3d** at 156°. The presence of dimeric products in the solid fraction of the reaction product from which 1-azidocarbonylazepine (**1e**) was obtained<sup>4</sup> also seems likely. The generality of the formation of ring system **3** is clearly demonstrated by its preparation from four different azepines.

The stability of system **3** is illustrated by the high melting points of its derivatives and by its resistance to strong mineral acid. Hydrolysis of 13,14-dicyano-13,14-diazatricyclo[6.4.1.1<sup>2,7</sup>]tetradeca-3,5,9,11-tetraene (**3a**) with 50% sulfuric acid at 100–120° proceeds in two stages through the biscarbamoyl derivative **3e** to the parent diamine **3f**. The latter is produced immediately when the bis-*t*-butoxycarbonyl derivative **3d** is treated with hydrogen bromide in glacial acetic acid.<sup>6</sup> The common difunctional derivatives **3g–u** of 13,14-diazatricyclo[6.4.1.1<sup>2,7</sup>]tetradeca-3,5,9,11-tetraene (**3f**) were prepared by conventional methods, and their analytical and spectral properties clearly indicate their relationship to **3f**.

The concerted formation of the (6 + 6) addition products **3a–d** from the monocycles **1a–d** is a thermally forbidden process according to the Woodward–Hoffmann rules.<sup>6</sup> The proposed (2 + 6) addition of tetracyanoethylene to 1-ethoxycarbonylazepine, **1b**,<sup>7</sup> has since been shown to be the normal thermally allowed (2 + 4) Diels–Alder addition.<sup>8</sup> The same results were obtained for a series of substituted 1-methoxycarbonylazepines, **1f**, with tetracyanoethylene.<sup>9</sup> It therefore seems reasonable that the thermal formation of structures **3** from **1** must involve an allowed intermediate (2 + 4) *endo* Diels–Alder product or a (4 + 6) *exo* product (e.g., **2**)<sup>1c</sup> which rearranges to the symmetrical isomer at higher temperatures. In our case (**1a** → **3a**) the symmetrical compound arises solely by rearrangement of the dimer of **1a**.

The proof of structure **3a** is based upon these observations. (1) Zinc dust distillation of **3a** at 350° produces aniline in low yield as the only volatile product.

(2) The parent diamine **3f** readily absorbs 4 molar equiv of hydrogen on hydrogenation in dilute hydrochloric acid over platinum oxide. The relationship of the octahydro derivative, 13,14-diazatricyclo[6.4.1.1<sup>2,7</sup>]tetradecane (**4a**), to **3f** and to the simple difunctional derivatives (**4b–g**) is apparent from their analytical and spectral properties.

(3) In contrast to their precursor, the dimer of **1a**, compounds **3** show only weak carbon–carbon double bond absorption in the 1600-cm<sup>-1</sup> region of the infrared spectrum. This fact, coupled with polarization studies<sup>10</sup> on the intense Raman band at 1615 cm<sup>-1</sup>

observed in compounds **3c** and **f** (CHCl<sub>3</sub> solution), can be accounted for by the symmetrical diene vibration of the proposed centrosymmetric C<sub>2h</sub> structure.

(4) The constancy of position and intensity of the ultraviolet maxima of compounds **3** in the 230–240-mμ region (ε 9500–21,000) (Table I) is consistent with the presence of two independent cisoid diene chromophores<sup>11</sup> rather than azepine, enamine, or enamide functions.<sup>12</sup> This absorption remains constant even in the dihydrochloride of **3f** and the monomethiodide of **3c**, indicating that the nitrogen atoms are isolated from the diene chromophores.<sup>12b,e,1</sup> In most cases, two maxima separated by 5–8 mμ and of approximately the same intensity can be resolved (Table I). In two examples (**3g**, **3k**) the extra chromophores are attributed to independent absorption by the nitrogen substituent. As expected, the saturated compounds **4** do not show diene absorption in the ultraviolet.

(5) The simple nmr spectra of these compounds enable the protons to be assigned readily. In compounds **3** the eight-proton vinyl signal usually appears as a broad singlet in the τ 3.5–4.0 region, while the four tertiary bridgehead protons adjacent to nitrogen are observed in the τ 5.2–5.8 region. In compounds **4** the vinyl proton signals of **3** are replaced by a broad 16-proton methylene multiplet near τ 8.3, and the bridgehead protons are now shifted upfield by 1.0–1.5 ppm. These generalizations are illustrated for the parent compounds **3f** and **4a** in Figures 1 and 2. The rigidity of system **3** provides an ideal case in which to study the effects of nitrogen substituents on nearby proton signals.<sup>13</sup> The four equatorial bridgehead

<sup>a</sup> Recorded at 60 Mc/sec on a Varian Associates A-60 spectrometer. Signals are recorded in cycles per second downfield from internal tetramethylsilane as singlets unless otherwise noted: d, doublet; t, triplet; q, quartet; m, multiplet. <sup>b</sup> Charged nitrogen produces a complex multiplet for the diene proton signals. <sup>c</sup> External tetramethylsilane calibration 4FK = CF<sub>3</sub>ClOCOCF<sub>3</sub>Cl. <sup>d</sup> Diene protons appear as a broad singlet superimposed upon the —CH=CH<sub>2</sub> system multiplet. <sup>e</sup> C<sub>10</sub>H<sub>17</sub> = 1-adamantyl. <sup>f</sup> Two distinct sets of bridgehead protons are seen because of the chemical nonequivalence of the two nitrogen atoms.

protons are quite sensitive to substituents on nitrogen and show the expected dependence of chemical shift upon substituent electronegativity. With simple linear

substituents (e.g., H, NO) a single, broad, unresolved signal is observed. With a cyano or alkyl substituent the bridgehead proton signal is a doublet (*J* = 4–6 cps). The origin of this splitting is the adjacent vinyl proton since the more intense member of the doublet lies on the downfield side and in some cases the vinyl region

200 (1966); (b) the rigid boat-ring piperazines in the 2,5-diazabicyclo-[2.2.1]heptane system, P. S. Portoghesi and A. A. Mikhail, *J. Org. Chem.*, **31**, 1059 (1966).

Figure 1 (top). Proton spectrum (60 Mc/sec) of 13,14-diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradeca-3,5,9,11-tetraene (3f) (500-cps sweep width).

Figure 2 (bottom). Proton spectrum (60 Mc/sec) of 13,14-diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradecane (4a) (250-cps sweep width).

becomes resolved into a complex multiplet. Alkoxy-carbonyl and acyl substituents cause the bridgehead protons to exhibit two broad signals equal in area and separated by 8–60 cps. This is clearly a case of amide isomerism in which two of the bridgehead protons have a different chemical shift from the other two.<sup>14</sup> Collapse of these two signals to a single broad signal was observed at temperatures of 60–100° in the case of the alkoxy-carbonyl derivatives 3b and 3d, but not in the acyl derivative 3m. Protonation or quaternization of one or both nitrogen atoms of system 3 resolves the usual broad vinyl signal into a complex multiplet. Obviously, the proximity of a further substituent increases the nonequivalence of the central and terminal protons of the diene system. These observations are summarized in Table II.

(6) The mass spectra of the unsaturated compounds 3 confirm the expected molecular weights and consistently exhibit half-parent ions as the base peak unless the nitrogen substituent is more readily fragmented. The lower mass values fall into a pattern characteristic of the azepine. Clearly, structure 3 undergoes ready fragmentation into azepinium ions<sup>15</sup> C<sub>6</sub>H<sub>5</sub>NR<sup>+</sup> (5).

The mass spectra of compounds 4 also confirm their molecular weights and usually exhibit base peaks corresponding to protonated half-parent ions C<sub>6</sub>H<sub>11</sub>NR<sup>+</sup>

(14) In the case of the ethoxycarbonyl derivative 3b, Paquette<sup>16</sup> has incorrectly described the bridgehead signals as a doublet ( $J = 8.5$  cps). At 100 Mc/sec, the separation of the bridgehead signals increases to 16.5 cps in 3b, and to 17.0 cps in 3d, but is unaffected in 3c.

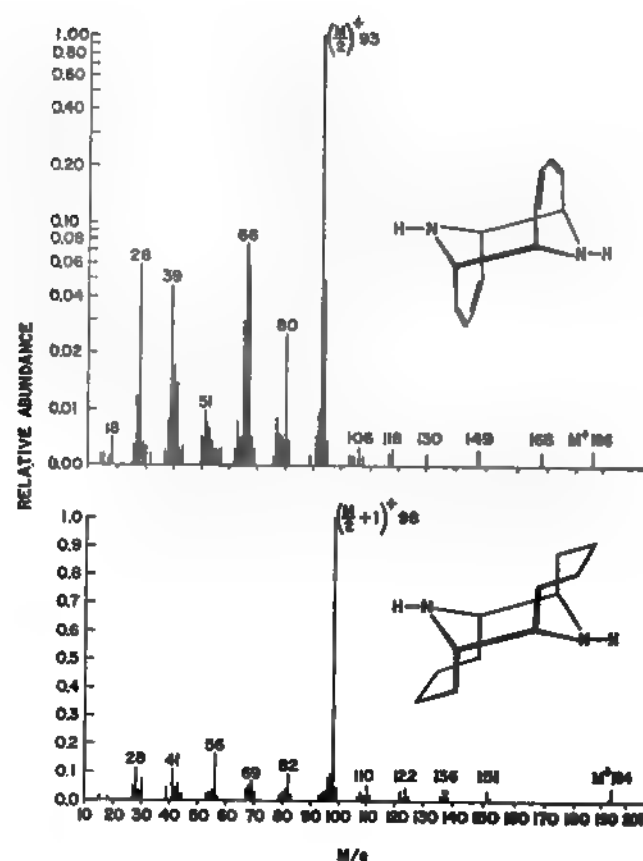

Figure 3 (top). Mass spectrum of 13,14-diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradeca-3,5,9,11-tetraene (3f).

Figure 4 (bottom). Mass spectrum of 13,14-diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradecane (4a).

(6). Their features are illustrated in Figures 3 and 4 for the parent compounds 3f and 4a.

(7) Examination of Dreiding models of 3f and 4a indicates that they are very rigid structures. The *trans* arrangement of the two four-carbon bridges is almost certainly favored over the *cis* arrangements 7 and 8 from the viewpoint of nonbonded interactions and the

unusual thermal stability of the compounds in the two series. The low dipole moment (0.57 D. in carbon tetrachloride) of 3c lends support to this structural assignment. "Angstrom ruler" calculations of the nonbonded H–H repulsion energies<sup>18</sup> place structure 8 (R = H) 63 kcal/mole above structure 4a in energy. Similar arguments have been advanced for the structure and stereochemistry of the parent carbocyclic system, tricyclo[6.4.1.1<sup>3,7</sup>]tetradeca-3,5,9,11-tetraene-13,14-dione.<sup>17</sup>

(8) The conversion of 1-cyanoazepine (1a) to 1-ethoxycarbonylazepine (1b) was observed according to Scheme 1. Paquette's compound 3b<sup>1c</sup> was prepared independently by the reaction of ethyl chloroformate with the parent diamine 3f. Direct photolysis of 3b

I

monitrile solution using a 2537-A source gave the dimer 1b, isolated in 12% yield by distillation. Generality of the photodecomposition of structure 3 examined for a number of derivatives. Under same conditions, the bis-*t*-butoxycarbonyl derivative reverted to the monomer 1d in 13% yield. In cases (3a, c, f, n, and r) recognizable products were obtained. The vibrations induced in the diene nophore on irradiation must be sufficient to break the relatively weak central bonds linking the monounits (*cf.* the mass spectrometry observations). Azepine can only be isolated if it is reasonably stable to further degradation. The amount of time required to cause the further cyclization of 1b to 9 (observed by Paquette<sup>18</sup> provides further evidence of the stability of this particular azepine. Under our irradiation conditions detectable amounts of bicyclic products like 9 were not observed as products from

Structure 3.

Further consequence of the geometry of ring systems 14 is seen in the formation of metallic complexes.

Both parent diamines 3f and 4a have their six-membered piperazine ring frozen into the chair conformation, bonding of both nitrogen atoms to the same cobalt atom is impossible. The cobalt(II) halides only form 1:1 complexes C<sub>12</sub>H<sub>14</sub>N<sub>2</sub>CoX<sub>2</sub> (X = Cl, Br) with 3f in ethanol solution. With larger anions complexes such as [C<sub>12</sub>H<sub>14</sub>N<sub>2</sub>]<sub>2</sub>Co(SCN)<sub>4</sub> and [C<sub>12</sub>H<sub>14</sub>N<sub>2</sub>]<sub>2</sub>Co(ClO<sub>4</sub>)<sub>2</sub>·4H<sub>2</sub>O are produced. Analytical, spectroscopic, and magnetic evidence suggests that the halides thiocyanate contain tetrahedral cobalt(II).<sup>19</sup> Attempts to produce cobalt(II) complexes of the more rigid compound 4a were unsuccessful. Reaction of cobalt(II) chloride hexahydrate with 4a produced the monohydrochloride of 4a.

Quaternization of the dimethyl derivatives 3c and 4c in both systems proceeds under moderately vigorous conditions to form the monomethiodides 10 and 11.<sup>1b,d</sup> The formation of only monoquaternary derivatives is

not unusual and has been observed with other bridged piperazines.<sup>20</sup> The Hofmann elimination on 10 proceeds in up to 92% yield and produces an unstable solid diamine, C<sub>15</sub>H<sub>20</sub>N<sub>2</sub>, whose properties appear to be consistent with a product of further cyclization, such as 12, rather than the cyclododecapentaene derivative 13 postulated by Hafner.<sup>1d</sup> The stable crystalline bis-methiodide of this product eliminates trimethylamine on further Hofmann reaction, indicating that a dimethylamino group is produced in the first elimination. The other products of this second Hofmann reaction are produced in low yield and have not yet been characterized.

## Experimental Section<sup>21</sup>

**13,14-Dicyano-13,14-diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradeca-3,5,9,11-tetraene (3a).** Crude 1-cyanoazepine dimer was purified by dissolving 200-g lots in boiling dichloromethane, filtering, and passing the filtrate down a 4-in. layer of Florisil packed into a chromatography column 3 ft in length and 4 in. in diameter. Each batch required a total of 10 l. of dichloromethane to elute the purified material, which was isolated by evaporation. A 5-l., four-necked Morton flask equipped with mechanical stirrer, thermometer, two hot water reflux condensers, and a heating mantle was charged with practical grade naphthalene (1000 g) and flushed with nitrogen. After the naphthalene had melted, the stirrer was started, and at a liquid temperature of 140°, powdered 1-cyanoazepine dimer (200 g) was added rapidly down one condenser. The dimer dissolved in the hot naphthalene, and when the temperature of the mixture reached 190°, a mildly exothermic reaction began in which the product precipitated and the temperature rose spontaneously to 210° where it was maintained for 30 min. After the mixture had cooled to 100°, it was diluted with 2500 ml of benzene and filtered. The brown finely crystalline residue of 13,14-dicyano-13,14-diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradeca-3,5,9,11-tetraene was washed with a further 1250 ml of benzene and air dried. The yield of almost pure product was 137.0–145.6 g (69–73%). Analytically pure material was obtained by continuous chromatography using an extractor 3 ft in height and 4 in. in diameter with dichloromethane as the eluent. The column was packed successively with 3 in. of 4-mm glass beads, 0.5 in. of fine silica sand, 3 in. of Florisil, and 14.5 g of colored product. Elution for 96 hr produced 5.38 g of pure

(21) Melting points are uncorrected and were determined in a Mel-Temp capillary apparatus. Infrared spectra in potassium bromide, Nujol, or solution media were determined on Perkin-Elmer 21 and 221 instruments. Raman spectra were determined on a Cary Model 83 spectrophotometer. Dipole moments were measured in solution on a WTW Dipolimeter Type DMO1. Molecular weights and mass spectra were determined by direct injection into a CEC 21-103 instrument.

white, finely crystalline dicyano compound **3a**, mp  $>400^{\circ}$  dec;  $\nu_{\text{max}}^{\text{KBr}}$  3040 (CH=CH), 2210 (C≡N), 1660, and 1625  $\text{cm}^{-1}$  (C=C);  $m/e$  236 (parent), 208, 195, 194, 193, 181, 169, 168, 167, 153, 144, 131, 119, 118 (base peak), 105, 91, 69, 57, and 55.

*Anal.* Calcd for  $\text{C}_{14}\text{H}_{12}\text{N}_4$ : C, 71.16; H, 5.12; N, 23.72. Found: C, 71.03, 71.36; H, 5.14, 5.13; N, 23.77, 23.74.

An intimate mixture of 13,14-dicyano-13,14-diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradeca-3,5,9,11-tetraene (1.0 g) and zinc dust (10 g) was heated in a pyrolysis tube at  $350^{\circ}$  for 30 min. The distillate (0.1 ml) was identified as aniline by infrared spectrum, azo dye formation, and gas chromatography.

**13,14-Biscarbamoyl-13,14-diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradeca-3,5,9,11-tetraene (3e).** A mixture of 13,14-dicyano-13,14-diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradeca-3,5,9,11-tetraene (5.6 g) and 50% sulfuric acid (50 ml) was stirred under nitrogen at  $100\text{--}120^{\circ}$  for 6 hr. The mixture was cooled, neutralized with sodium bicarbonate, and filtered to leave a residue of the crude biscarbamoyl compound (5.25 g, 81%). Two recrystallizations from 20-ml portions of 1:2 dichlorotetrafluoroacetone–water with Darco G-60 treatment produced 2.4 g of fine white crystalline 13,14-biscarbamoyl-13,14-diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradeca-3,5,9,11-tetraene, mp  $>300^{\circ}$  dec;  $\nu_{\text{max}}^{\text{KBr}}$  3420, 3300, 3160, 1650, and 1585  $\text{cm}^{-1}$  (NCONH<sub>2</sub>);  $m/e$  272 (parent), 229, 228, 212, 211, 186, 185, 183, 170, 169, 168, 167, 154, 149, 144, 143, 136 (base peak), 123, 118, 106, 97, 93, 87, 85, 83, 81, 69, 57, 56, 55, 43, 42, 41, 31, 29, 28, 27, and 18.

*Anal.* Calcd for  $\text{C}_{14}\text{H}_{14}\text{N}_4\text{O}_2$ : C, 61.75; H, 5.92; N, 20.58. Found: C, 62.08, 62.02; H, 6.17, 5.98; N, 20.01.

A 2:1 mixture of *p*-toluenesulfonic acid monohydrate and water was equally effective in promoting this hydrolysis.

**13,14-Diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradeca-3,5,9,11-tetraene (3f).** A 5-l., four-necked Morton flask equipped with heating mantle, mechanical stirrer, two long reflux condensers, nitrogen inlet, and thermometer was charged with a cold mixture of sulfuric acid (500 ml), water (1000 ml), and 13,14-dicyano-13,14-diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradeca-3,5,9,11-tetraene (140 g). The apparatus was flushed with nitrogen, and the temperature of the mixture was gradually raised to  $110\text{--}120^{\circ}$  where it was maintained for 24 hr. The dark brown mixture was cooled to  $50^{\circ}$ , poured onto 600 g of ice, mixed with Celite, and filtered. The residue was discarded, and the filtrate was stirred and cooled in a 4-l. erlenmeyer flask while it was cautiously basified with sodium hydroxide ( $\sim 750$  g). The precipitate was filtered at room temperature, air dried, and extracted with chloroform in a Soxhlet apparatus. Evaporation of the dried chloroform extracts yielded 49–63 g (45–58%) of yellow powdery diamine **3f**, mp  $141\text{--}145^{\circ}$  dec, which was sufficiently pure for most purposes. Analytically pure material was obtained by repeated crystallization from water with Darco G-60 treatment (50% recovery) or by sublimation at  $110^{\circ}$  (0.1 mm) (87% recovery). Pure 13,14-diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradeca-3,5,9,11-tetraene forms fine white crystals, mp  $147\text{--}148^{\circ}$  dec;  $\nu_{\text{max}}^{\text{KBr}}$  3420, 3290 (NH), 3030 (CH=CH), and  $1655\text{ cm}^{-1}$  (C=C).

*Anal.* Calcd for  $\text{C}_{14}\text{H}_{12}\text{N}_4$ : C, 77.38; H, 7.58; N, 15.04. Found: C, 77.33; H, 7.72; N, 15.10, 14.84.

Derivatives of this diamine were prepared as follows.

**13,14-Diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradeca-3,5,9,11-tetraene Dihydrochloride (3f·2HCl).** A suspension of the diamine **3f** (2.25 g) in acetone (20 ml) was treated with concentrated hydrochloric acid (3.2 ml). The precipitate was recrystallized from 1% hydrochloric acid (20 ml) and acetone (350 ml). The white crystals of the dihydrochloride (1.38 g) had mp  $>300^{\circ}$  dec;  $\nu_{\text{max}}^{\text{KBr}}$  2940–2680 (NH<sub>2</sub><sup>+</sup>), 1630 (C=C), and 1550  $\text{cm}^{-1}$  (NH<sub>2</sub><sup>+</sup>).

*Anal.* Calcd for  $\text{C}_{14}\text{H}_{14}\text{N}_4\text{Cl}_2$ : C, 55.60; H, 6.22; N, 10.81. Found: C, 55.88; H, 6.38; N, 11.16.

**13,14-Dinitroso-13,14-diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradeca-3,5,9,11-tetraene (3g).** A mixture of the diamine **3f** (1.86 g, 0.01 mole), water (10 ml), and concentrated hydrochloric acid (3.3 ml, 0.03 mole) was stirred at  $0^{\circ}$  and treated with a solution of sodium nitrite (1.52 g, 0.022 mole) in water (5 ml) for 1.5 hr. Two recrystallizations of 0.30 g of the crude product from 60–80 ml of ethanol produced 0.12 g of pure dinitroso compound as golden needles, mp  $>250^{\circ}$  dec;  $\nu_{\text{max}}^{\text{KBr}}$  3030 (CH=CH), 1625 (C=C), 1450, 1370, and 1055  $\text{cm}^{-1}$  (N=N=O);  $m/e$  184 (parent – 2NO), 105, 93, 92 (base peak, half parent – NO), 80, 79, 78, 66, 65, 63, 52, 51, 39, 38, 30 (NO), and 27.

*Anal.* Calcd for  $\text{C}_{14}\text{H}_{12}\text{N}_4\text{O}_2$ : C, 59.01; H, 4.95; N, 22.94. Found: C, 59.07, 59.02; H, 5.03, 5.14; N, 22.72.

**13,14-Dimethyl-13,14-diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradeca-3,5,9,11-tetraene (3c).** Methyl iodide (80 ml) at  $0^{\circ}$  in a polymer tube was treated gradually with diamine **3f** (8.0 g). The tube was sealed and heated overnight at  $100^{\circ}$ . The contents of the tube were evap-

orated to dryness, stirred with 30 ml of water, and basified with 25% sodium hydroxide. The dried precipitate was sublimed at  $125^{\circ}$  (0.1 mm) to provide colorless crystals of the dimethyl compound (6.70 g, 73%), mp  $165\text{--}166^{\circ}$  dec;  $\nu_{\text{max}}^{\text{KBr}}$  3080, 3030 (CH=CH), and 1450  $\text{cm}^{-1}$  (NCH<sub>3</sub>);  $m/e$  214 (parent), 108, 107 (base peak), 106, 95, 94, 93, 92, 91, 82, 81, 80, 79, 78, 77, 67, 66, 65, 64, 63, 55, 54, 53, 52, 51, 50, 44, 43, 42, 41, 40, 39, 38, 28, 26, 18, and 15.

**13,14-Bisethoxycarbonyl-13,14-diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradeca-3,5,9,11-tetraene (3b) and Its Photolysis to 1-Ethoxycarbonylazepine (3a).** A suspension of 13,14-diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradeca-3,5,9,11-tetraene (3f) (7.44 g) and anhydrous sodium carbonate (4.14 g) in ether (70 ml) was stirred at room temperature and treated dropwise with a solution of ethyl chloroformate (8.50 g) in ether (100 ml). After standing overnight, the solvent was evaporated, and the residue was stirred with water and filtered. Two recrystallizations of the crude damp yellow product from ethanol (20 ml) yielded 7.72 g (59%) of fine white crystalline bisethoxycarbonyl derivative,<sup>24</sup> mp 196.5–197.5° dec;  $\nu_{\text{max}}^{\text{KBr}}$  3070, 3030 ( $\text{CH}=\text{CH}$ ), 1660 ( $\text{NCO}_2\text{C}_2\text{H}_5$ ), and 1650  $\text{cm}^{-1}$  ( $\text{C}=\text{C}$ ); *m/e* 330 (parent), 166, 165 (base peak), 152, 137, 130, 128, 118, 117, 115, 108, 106, 104, 103, 2, 80, 66, 65, and 29.

*l.* Calcd for  $\text{C}_{18}\text{H}_{22}\text{N}_2\text{O}_4$ : C, 65.44; H, 6.71; N, 8.48. Found: C, 65.39, 65.66; H, 6.52, 6.54; N, 8.65, 8.76. A mixture of the bisethoxycarbonyl derivative 3b (4.1 g) and nitrile (400 ml) was agitated with a nitrogen bubbler in a water-d (12°) quartz apparatus and photolyzed with a low-pressure mercury 2537-A source. The progress of the reaction was followed by gas chromatography at 140° on a 6-ft, 20% silicone 200-80 AWFB column and by ultraviolet spectroscopy in acetone solution. The reaction was complete after 24-hr irradiation. After evaporation of the solvent, the dark red residue was distilled (0.1 mm) to give 1-ethoxycarbonylazepine (1b) as an orange oil (1.5 g, 12%) identified by gas chromatography retention time (min) and infrared and nmr spectra. This material was identical to that prepared by reaction of benzene with ethoxycarbonylbenzene.<sup>12,13</sup> Similar irradiation of compounds 3a, c, f, and n

produced tars from which the corresponding azepines (1) were not obtained.

**13,14-Bis-*t*-butoxycarbonyl-13,14-diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradeca-3,5,9,11-tetraene (3d) and Its Photolysis to 1-*t*-Butoxycarbonylazepine (1d).** 1-*t*-Butoxycarbonylazepine (1d) was prepared according to Hafner<sup>12</sup> and Cotter and Beach<sup>13</sup> from a solution of *t*-butyl azidoformate (50 g, Aldrich) in benzene (4 l.) at 125° for 2 hr. In addition to the azepine (12.80 g) (63% yield based on azidoformate not converted to oxazolidone), bp 40–60° (0.1 mm), there was isolated 22.4 g of hexane-insoluble 5,5-dimethyl-2-oxazolidone,<sup>26</sup> mp 80–81°, produced by intramolecular insertion of the nitrene.<sup>27</sup> A 7.2-g charge of the azepine was degassed, sealed *in vacuo*, and heated at 156° for 2 hr. The contents of the tube were rinsed out with hexane and filtered. The insoluble residue (2.75 g, 38%) of bis-*t*-butoxycarbonyl derivative 3d was recrystallized twice from 50 ml of 1:1 ethanol–water with Darco G-60 treatment to give colorless needles of the pure compound, mp 205–206° dec;  $\nu_{\text{max}}^{\text{KBr}}$  3030, 3010 ( $\text{CH}=\text{CH}$ ), and 1680  $\text{cm}^{-1}$  ( $\text{NCO}_2\text{C}(\text{CH}_3)_3$ ); *m/e* 386 (parent), 274, 230, 193 (half-parent), 186, 185, 168, 138, 137, 130, 124, 120, 118, 107, 106, 94, 93, (base peak), 92, 81, 80, 79, 69, 67, 66, 65, 58, 57, 56, 55, 53, 51, 44, 43, 42, 41, 40, 39, 38, 29, 27, and 15.

*Anal.* Calcd for  $\text{C}_{28}\text{H}_{40}\text{N}_2\text{O}_4$ : C, 68.37; H, 7.82; N, 7.25. Found: C, 68.35; H, 7.58; N, 7.36, 7.38.

Chemical proof of the structure of 3d was obtained by conversion to 3f with hydrogen bromide in glacial acetic acid.<sup>5</sup> When 0.5 g of the bis-*t*-butoxycarbonyl compound was added to 5 ml of 30%  $\text{HBr}-\text{CH}_2\text{CO}_2\text{H}$  (Eastman) there was an immediate evolution of gas ( $\text{C}_4\text{H}_8$  and  $\text{CO}_2$ ). The mixture was poured onto ice, basified with sodium hydroxide, and extracted with chloroform. The chloroform extracts yielded the parent diamine 3f, identified by mixture melting point and infrared and nmr spectra.

The bis-*t*-butoxycarbonyl derivative (2.0 g) was dissolved in 250 ml of acetonitrile and photolyzed in the same way as the bisethoxycarbonyl derivative. Recovered starting material weighed 0.80 g, and after distillation 0.16 g (13%) of 1-*t*-butoxycarbonylazepine (1d) was obtained, identified by comparison of infrared and nmr spectra with those of authentic material.

**13,14-Bischloroacetyl-13,14-diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradeca-3,5,9,11-tetraene (3e).** A solution of diamine 3f (1.86 g) and triethylamine (2.50 g) in benzene (30 ml) was treated with a solution of chloroacetyl chloride (2.50 g) in benzene (10 ml). The product was isolated by evaporation and recrystallized from a mixture of trifluoroacetic acid (35 ml) and water (200 ml), yield 2.54 g (75%) of the bischloroacetyl derivative, mp >215° dec;  $\nu_{\text{max}}^{\text{KBr}}$  3030 ( $\text{CH}=\text{CH}$ ) and 1660  $\text{cm}^{-1}$  ( $\text{NCOCH}_2\text{Cl}$ ).

In an analytical scale experiment using an atmospheric pressure hydrogenator, 4 molar equiv of hydrogen was absorbed at 25° (760 mm) over 5.5 hr.

The dihydrochloride and dihydrobromide of 4a were prepared by the same procedure as the dihydrochloride of 3f. 13,14-Diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradecane dihydrochloride forms white crystals, mp >320° dec;  $\nu_{\text{max}}^{\text{KBr}}$  2740, 2700, 2630, and 1575 cm<sup>-1</sup> (NH<sub>3</sub><sup>+</sup>); nmr (D<sub>2</sub>O)  $\tau$  5.30 (singlet, four NH<sub>3</sub><sup>+</sup> protons), 6.00 (multiplet, four tertiary protons), and 8.10 (multiplet, 16 CH<sub>2</sub> protons).

*Anal.* Calcd for C<sub>18</sub>H<sub>24</sub>N<sub>2</sub>Cl<sub>2</sub>: C, 53.94; H, 9.06. Found: C, 53.88; H, 8.99.

13,14-Diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradecane dihydrobromide is a white powder, mp >320° dec;  $\nu_{\text{max}}^{\text{KBr}}$  2820–2600 and 1570 cm<sup>-1</sup> (NH<sub>3</sub><sup>+</sup>); nmr (D<sub>2</sub>O)  $\tau$  5.34 (singlet, four NH<sub>3</sub><sup>+</sup> protons), 6.02 (multiplet, four tertiary protons), and 8.18 (multiplet, 16 CH<sub>2</sub> protons); *m/e* 356, 355, 354 (parents), 194, 138, 137, 124, 123, 122, 111, 110, 109, 108, 107, 106, 99, 98 (base peak), 97, 96, 95, 94, 93, 91, 84, 83, 82, 81, 80, 79, 69, 68, 67, 57, 56, 55, 54, 53, 44, 43, 42, 41, 39, 30, 29, 28, 27, and 18.

*Anal.* Calcd for C<sub>18</sub>H<sub>24</sub>N<sub>2</sub>Br<sub>2</sub>: C, 40.47; H, 6.79; N, 7.78. Found: C, 40.71; H, 6.79; N, 7.98.

13,14-Diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradecane monohydrochloride, described below as a reaction product from diamine 4a and cobalt(II) chloride, was prepared independently by (a) neutralization of 4a with 1 equiv of hydrochloric acid and (b) mixing equimolar amounts of 4a and its dihydrochloride in chloroform.

**13,14-Dinitroso-13,14-diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradecane (4b).** The crude nitroso compound, prepared in the same way as 3g, was obtained in 92% yield after two recrystallizations from aqueous ethanol as pale yellow crystals, mp 180–182.5° dec;  $\lambda_{\text{max}}^{\text{CH}_2\text{OH}}$  363 m $\mu$  ( $\epsilon$  153), 355 m $\mu$  ( $\epsilon$  146), and 248 m $\mu$  ( $\epsilon$  12,300);  $\nu_{\text{max}}^{\text{KBr}}$  1460, 1450, 1430, 1370, and 1355 cm<sup>-1</sup> (N=N=O); nmr (CDCl<sub>3</sub>)  $\tau$  4.89 (multiplet, four tertiary protons) and 8.60 (multiplet, 16 CH<sub>2</sub> protons).

*Anal.* Calcd for C<sub>18</sub>H<sub>20</sub>N<sub>2</sub>O<sub>2</sub>: C, 57.11; H, 7.99; N, 22.21. Found: C, 57.32, 57.17; H, 7.79, 7.68; N, 22.24, 22.12.

**13,14-Dimethyl-13,14-diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradecane (4c).** A mixture of diamine 4a (6.0 g), methanol (100 ml), anhydrous sodium carbonate (3.50 g), and methyl iodide (20 ml) was heated under reflux for 20 hr. The mixture was evaporated to dryness; the residue was stirred with water (35 ml), cooled to 0°, and filtered. The crude dimethyl compound was purified by sublimation at 100–110° (0.1 mm). The colorless waxy product (6.66 g, 97%) had mp 125–130°;  $\nu_{\text{max}}^{\text{KBr}}$  2780 and 1440 cm<sup>-1</sup> (NCH<sub>3</sub>); nmr (CCl<sub>4</sub>)  $\tau$  7.35 (singlet, four tertiary protons), 7.45 (singlet, six NCH<sub>3</sub> protons), and 7.90–8.50 (broad multiplet, 16 CH<sub>2</sub> protons); *m/e* 222 (parent), 208, 207 (parent – CH<sub>3</sub>), 192, 180, 179, 166, 165, 151, 138, 124, 123, 122, 113, 112 (base peak, half-parent + H), 111, 110, 109, 108, 98, 97, 96, 95, 94, 84, 83, 82, 81, 70, 68, 67, 58, 57, 55, 42, 41, 39, 30, 29, 28, 27, and 15.

*Anal.* Calcd for C<sub>20</sub>H<sub>26</sub>N<sub>2</sub>: C, 75.61; H, 11.79; N, 12.60. Found: C, 75.78; H, 11.69; N, 12.75.

**13,14-Diethyl-13,14-diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradecane (4d).** The above procedure was employed substituting ethanol for methanol and ethyl iodide for methyl iodide. The yield of pure diethyl derivative, bp 95° (0.1 mm), was 2.15 g (86%) of colorless crystals, mp 35–37°;  $\nu_{\text{max}}^{\text{KBr}}$  2960–2850, 1465, and 1440 cm<sup>-1</sup> (NC<sub>2</sub>H<sub>5</sub>); nmr (CCl<sub>4</sub>)  $\tau$  7.12 (quartet, *J* = 7 cps, + broad multiplet, four NCH<sub>2</sub> + four tertiary protons), 8.0–8.60 (broad multiplet, 16 CH<sub>2</sub> protons), and 8.96 (triplet, *J* = 7 cps, six CH<sub>3</sub> protons).

*Anal.* Calcd for C<sub>22</sub>H<sub>30</sub>N<sub>2</sub>: C, 76.74; H, 12.08; N, 11.19. Found: C, 76.90; H, 11.79; N, 11.43.

(29) Our freshly sublimed and analytically pure material contracted near 95° and melted at 125–130°. Paquette<sup>10,34</sup> observed mp 128–145° for sublimed product and mp 148–150° for sublimed product recrystallized from Skellysolve B at 0 to –5°. On the basis of direct comparison of analytical and spectral data of these differently prepared samples we have concluded that they are identical.

**13,14-Dibenzoyl-13,14-diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradecane (4e).** A mixture of diamine 4a (1.94 g, 0.01 mole) and 10% sodium hydroxide (40 ml) was shaken with benzoyl chloride (5 ml). The crude product was recrystallized twice from a mixture of ethanol and chloroform, mp 319.5–320.5° dec;  $\nu_{\text{max}}^{\text{KBr}}$  3070 (C<sub>6</sub>H<sub>5</sub>), 1635, and 1595 cm<sup>-1</sup> (C<sub>6</sub>H<sub>5</sub>CO); nmr (CDCl<sub>3</sub>)  $\tau$  2.65 (doublet, *J* = 6 cps, ten aromatic protons), 5.04 (multiplet, two tertiary protons), 6.36 (multiplet, two tertiary protons), and 8.33 (multiplet, 16 CH<sub>2</sub> protons). Temperature probe nmr experiments between –60 and +126° did not cause any coalescence of the tertiary proton signals. The mass spectrum showed *m/e* 402 (parent), 298, 297, 296, 295 (base peak), 294, 293, 292, 291, 289, 277, 276, 275, 202, 201, 200, 199, 198, 197, 105, 85, 81, 71, 69, 57, and 55.

*Anal.* Calcd for C<sub>28</sub>H<sub>26</sub>N<sub>2</sub>O<sub>2</sub>: N, 6.96. Found: N, 6.72. **13,14-Bisphenylcarbamoyl-13,14-diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradecane (4f).** The crude bisphenylcarbamoyl derivative, obtained in 94% yield by a procedure analogous to that used to prepare 3p, was purified by Soxhlet extraction with ethanol as a white powder, mp 374–375° dec;  $\nu_{\text{max}}^{\text{KBr}}$  3320 (NH), 3060 (C<sub>6</sub>H<sub>5</sub>), 1640, 1595, 1530, and 1505 cm<sup>-1</sup> (NCONHC<sub>6</sub>H<sub>5</sub>).

*Anal.* Calcd for C<sub>44</sub>H<sub>38</sub>N<sub>4</sub>O<sub>2</sub>: C, 72.19; H, 7.46; N, 12.95; mol wt, 432. Found: C, 72.12, 72.06; H, 7.48, 7.55; N, 13.08, 13.20; mol wt, 432.

**13,14-Bisphenylthiocarbamoyl-13,14-diazatricyclo[6.4.1.1<sup>3,7</sup>]tetradecane (4g).** The white crystalline bisphenylthiocarbamoyl derivative obtained analogously to 3q in 84% yield was purified by Soxhlet extraction with ethanol. The pure material had mp 289–289.5° dec;  $\nu_{\text{max}}^{\text{KBr}}$  3070 (C<sub>6</sub>H<sub>5</sub>), 1605, 1505, 1450, 1375, and 1340 cm<sup>-1</sup> (NCSNHC<sub>6</sub>H<sub>5</sub>).
